Bailey & Love's
SHORT
PRACTICE of
SURGERY

26th EDITION

Sebaceous horn

(The owner, the widow Dimanche, sold water-cress in Paris)

A favourite illustration of Hamilton Bailey and McNeill Love, and well known to readers of earlier editions of Short Practice.

Bailey & Love's SHORT PRACTICE of SURGERY

26th EDITION

Edited by

NORMAN S. WILLIAMS MS FRCS FMed Sci

Professor of Surgery and Director of Surgical Innovation,
Barts and the London School of Medicine and Dentistry,
Queen Mary, University of London and President,
The Royal College of Surgeons of England, London, UK

CHRISTOPHER J.K. BULSTRODE MCh FRCS(T&O)

Emeritus Professor, University of Oxford, Oxford, UK

P. RONAN O'CONNELL, MD FRCSI, FRCPS Glas.,

Head, Surgery and Surgical Specialties,
UCD School of Medicine and Medical Sciences
Consultant Surgeon, St Vincent's University Hospital,
Dublin, Ireland

Contributors	viii
Preface	xiii
Acknowledgements	xiv
Sayings of the great	xvi

PART ONE: PRINCIPLES

1. Metabolic response to injury <i>Kenneth Fearon</i>	3
2. Shock and blood transfusion <i>Karim Brohi</i>	13
3. Wounds, tissue repair and scars <i>Michael Earley</i>	24
4. Basic surgical skills and anastomoses <i>William E. G. Thomas</i>	33
5. Surgical infection <i>Peter Lamont</i>	50
6. Surgery in the tropics <i>Pradip K Datta, Pawanindra Lal and Sanjay De Bakshi</i>	68
7. Principles of laparoscopic and robotic surgery <i>Ara Darzi and Sanjay Purkayastha</i>	93
8. Principles of paediatric surgery <i>Anthony Lander</i>	105
9. Principles of oncology <i>Robert JC Steele and Alastair J Munro</i>	125
10. Surgical audit and clinical research <i>Jonathan Earnshaw and Birgit Whitman</i>	147
11. Surgical ethics and law <i>Robert Wheeler</i>	155

12. Patient safety <i>Frank Keane</i>	161
--	-----

PART TWO: INVESTIGATION AND DIAGNOSIS

13. Diagnostic imaging <i>Matthew Matson, Gina Allen and Niall Power</i>	171
14. Gastrointestinal endoscopy <i>James Lindsay</i>	196
15. Tissue diagnosis <i>Roger Feakins</i>	213

PART THREE: PERIOPERATIVE CARE

16. Preoperative preparation <i>Medha Vanarase, Pierre Foex and Kevin Tremper</i>	229
17. Anaesthesia and pain relief <i>Vivek Mehta, Richard Langford and Jagannath Haldar</i>	238
18. Care in the operating room <i>Kath Jenkins and Hilary Edgcombe</i>	247
19. Perioperative management of the high-risk surgical patient <i>Mridula Rai and Kevin D Johnston</i>	255
20. Nutrition and fluid therapy <i>John MacFie</i>	261
21. Postoperative care <i>Jay Kini</i>	272
22. Day case surgery <i>Douglas McWhinnie and Ian Jackson</i>	281

PART FOUR: TRAUMA

23. Introduction to trauma <i>Bob Handley and Peter Giannoudis</i>	289
---	-----

24. Early assessment and management of trauma	301
<i>Dinesh Nathwani and Joseph Windley</i>	
25. Emergency neurosurgery	310
<i>Tony Belli and Harry Bulstrode</i>	
26. Neck and spine	326
<i>Ashley Poynton</i>	
27. Maxillofacial trauma	341
<i>Charles Perkins</i>	
28. Torso trauma	351
<i>Ken Boffard</i>	
29. Extremity trauma	364
<i>Parminder Singh</i>	
30. Burns	385
<i>Michael Tyler and Sudip Ghosh</i>	
31. Plastic and reconstructive surgery	401
<i>Tim Goodacre</i>	
32. Disaster surgery	417
<i>Mamoon Rashid</i>	

PART FIVE: ELECTIVE ORTHOPAEDICS

33. History taking and clinical examination in musculoskeletal disease	437
<i>Parminder J Singh and Hemant G Pandit</i>	
34. Sports medicine and sports injuries	463
<i>Gina Allen</i>	
35. The spine	470
<i>Chris Lavy and Gavin Bowden</i>	
36. Upper limb – pathology, assessment and management	485
<i>Vinay Takwale and Irfan Khan</i>	
37. Hip and knee	505
<i>Hemant G Pandit and Andrew Barnett</i>	
38. Foot and ankle	518
<i>Bob Sharpe</i>	
39. Musculoskeletal tumours	526
<i>Paul Cool</i>	
40. Infection of the bones and joints	541
<i>Martin McNally, Philippa Matthews and Philip Bejon</i>	
41. Paediatric orthopaedics	550
<i>Deborah Eastwood</i>	

PART SIX: SKIN AND SUBCUTANEOUS TISSUE

42. Skin and subcutaneous tissue	577
<i>Christopher Chan and Adam Greenbaum</i>	

PART SEVEN: HEAD AND NECK

43. Elective neurosurgery	605
<i>William Gray and Harry Bulstrode</i>	
44. The eye and orbit	622
<i>Colm O'Brien, Hugo Henderson and Jonathan Jagger</i>	
45. Cleft lip and palate: developmental abnormalities of the face, mouth and jaws	634
<i>William P Smith</i>	
46. The nose and sinuses	653
<i>Robert W Ruckley and Iain J Nixon</i>	
47. The ear	661
<i>Grant Bates</i>	
48. Pharynx, larynx and neck	674
<i>Rishi Sharma and Martin Birchall</i>	
49. Oropharyngeal cancer	706
<i>William P Smith</i>	
50. Disorders of the salivary glands	723
<i>William P Smith</i>	

PART EIGHT: BREAST AND ENDOCRINE

51. The thyroid and parathyroid glands	741
<i>Zygmunt H Krukowski</i>	
52. The adrenal glands and other abdominal endocrine disorders	778
<i>Tom WJ Lennard</i>	
53. The breast	798
<i>Richard Sainsbury</i>	

PART NINE: CARDIOTHORACIC

54. Cardiac surgery	823
<i>Jonathan R Anderson and Mustafa Zakkar</i>	
55. The thorax	850
<i>Ian Hunt and Carol Tan</i>	

PART TEN: VASCULAR

56. Arterial disorders	877
<i>Robert Sayers</i>	
57. Venous disorders	901
<i>Peter McCollum and Ian Chetter</i>	

58. Lymphatic disorders 923
Shervanthi Homer-Vanniasinkam and David A Russell

PART ELEVEN: ABDOMINAL

59. History and examination of the abdomen 941
Mohan de Silva and V Sitaram
60. Abdominal wall, hernia and umbilicus 948
Stephen J Nixon and Bruce Tulloh
61. The peritoneum, omentum, mesentery and retroperitoneal space 970
Charles H Knowles
62. The oesophagus 987
Derek Alderson
63. Stomach and duodenum 1023
John N Primrose and Timothy J Underwood
64. Bariatric surgery 1058
John Baxter
65. The liver 1065
Rahul S Koti, Sanjeev Kanoria and Brian R Davidson
66. The spleen 1087
O James Garden
67. The gall bladder and bile ducts 1097
Kevin Conlon
68. The pancreas 1118
Satyajit Bhattacharya
69. The small and large intestines 1143
Gordon Carlson and Jonathan Epstein
70. Intestinal obstruction 1181
Jim Hill

71. The vermiform appendix 1199
P Ronan O'Connell

72. The rectum 1215
Sue Clark

73. The anus and anal canal 1236
Peter Lunniss and Karen Nugent

PART TWELVE: GENITOURINARY

74. Urinary symptoms and investigations 1271
Christopher G Fowler

75. The kidneys and ureters 1282
Christopher G Fowler

76. The urinary bladder 1309
Freddie Hamdy

77. The prostate and seminal vesicles 1340
David E Neal and Greg L Shaw

78. Urethra and penis 1359
Ian Eardley

79. Testis and scrotum 1377
Ian Eardley

80. Gynaecology 1392
Stephen Kennedy and Enda McVeigh

PART THIRTEEN: TRANSPLANTATION

81. Transplantation 1407
J Andrew Bradley

- Appendix 1:
 Common instruments used in general surgery 1433
Pradip K Datta

- Index 1437

Preface

In this age of rapid electronic access to scientific papers and erudite surgical opinion one has to ask whether there is still a place for a comprehensive surgical textbook that takes several years to compile and risks losing its immediacy. The success of the 25th edition of *Bailey & Love* together with the numerous positive communications we have received since its publication suggest that the answer is very much in the affirmative. However, it is essential that in producing further editions cognisance is taken of what the “customer” wants. Consequently before preparing the 26th edition of this venerable text we conducted considerable market research as to what had succeeded in the previous edition, what had been omitted and how we could improve content and presentation. Readers from a range of backgrounds from undergraduates to hard bitten and, dare we say, cynical senior consultants were asked for their opinion. Their musings and frank criticisms were all taken very seriously and many of their suggestions were adopted for this edition. A few chapters were removed or consolidated into others; new chapters have been added focusing on the important topics of patient safety, day case surgery and bariatric surgery.

All existing chapters have been radically revised and have been thoroughly brought up to date. We have attempted to ensure more conformity with regard to illustrations; however, we have kept faith with Hamilton Bailey and McNeil Love’s original concept of ensuring clinical photographs are liberally used to not only enhance the text but more importantly illuminate a clinical point. Many new photographs have been introduced, some of which have been provided by our readers, which is very much a *Bailey & Love* tradition.

Although we have been ruthless in removing old material we make no excuse for retaining the odd original pen drawing taken from the first few editions. This is not just for nostalgia’s sake but because they illustrate a pertinent point not easily captured by a modern photograph. Another tradition beloved of readers has of course been the autobiographical notes. These have all been painstakingly researched and added to by Pradip Datta.

We recognise that despite very careful attention to detail by our authors there may be an occasional error in the text that we and our proof readers have failed to spot. It would not be

surprising in a text of this length. We apologise in advance for any errors and thank our eagle-eyed readers whom we know from experience will let us know of any that they find. This is a *Bailey & Love* tradition and we value all contributions that can improve accuracy.

Several editions ago we introduced the concept of learning objectives and summary boxes in order to help examination candidates in their revision. The feedback regarding these innovations was extremely positive and we have attempted to ensure that these are comprehensive, standardised and liberally dispersed through the text.

The authors of the chapters have been carefully chosen not just for their undoubted experience and expertise in their specialty but also their ability to write both accurately and succinctly. Writing is a skill honed by practice; it is a labour of love and takes time and patience to perfect. The best authors are like gifted musicians who, after numerous rehearsals, are able to deliver a perfect recital. It is our belief that our contributors have done just this and we the editors have attempted wherever possible to ensure there is a rhythm and harmony flowing through the pages. However, at the end of the day we appreciate it will be up to the audience to decide how successful we and our authors have been in this endeavour.

It has been a pleasure and privilege to edit this historic textbook beloved of so many students and trainees through the decades. However, we are conscious that previous reputation counts for very little unless the present product meets expectations and is relevant to the present era. This thought has always been in our minds when preparing the content of the 26th edition. We very much hope it fits the bill and fulfils your requirements whether you, the reader, are studying for an exam, checking on an area of practice that you may be unfamiliar with or just refreshing your memory about some forgotten fact or biographical detail.

Acknowledgements

Sometimes a new edition of *Bailey & Love* feels like a swan swimming swiftly but serenely across a lake. From afar it may look effortless (and beautiful we hope), but to those who are closer to the action you can glimpse the webbed feet paddling away furiously beneath the surface driving that swan forward. The three editors are one part of a huge orchestra too large to mention all by name. However, it is a pleasure to acknowledge some of the most notable amongst the players.

Gavin Jamieson initiated the new edition as commissioning editor under the supervision of Jo Koster, who then took over following Gavin's departure. Sarah Penny and Stephen Clausard took on the awesome responsibility of pulling all things 'manuscript-related' together. Susie Bond, Alyson Thomas and Theresa Mackie have done a great job with the copy editing and proof reading, while the index has been compiled ably by Christopher Boot. Mr Pradip Datta FRCS completely revamped the historical footnotes, going back all the way to the first edition to check that we had left no 'jewels' out of the crown. Mr Hemant Pandit FRCS, Dr Medha Vanarese FRCA and Mr Parminder Singh FRCS helped enormously with the commissioning and editing of the orthopaedic, anaesthetic and trauma chapters respectively.

Chapter 4, *Basic surgical skills and anastomoses*, contains some material from '*Basic surgical skills and anastomoses*' by David J. Leaper. The material has been revised and updated by the current author.

Chapter 5, *Surgical infection*, contains some material from '*Surgical infection*' by David J. Leaper. The material has been revised and updated by the current author.

Chapter 8, *Principles of paediatric surgery*, contains some material from '*Principles of paediatric surgery*' by Mark Stringer. The material has been revised and updated by the current author.

Chapter 11, *Surgical ethics and law*, contains some material from '*Surgical ethics*' by Len Doyal. The material has been revised and updated by the current author.

Chapter 16, *Preoperative preparation*, contains some material from '*Preoperative preparation*' by Lisa Leonard and Sarah J. Barton. The material has been revised and updated by the current authors.

Chapter 18, *Care in the operating room*, contains some material from '*Care in the operating room*' by Sunny Deo and Vipul Mandalia. The material has been revised and updated by the current authors.

Chapter 19, *Perioperative management of the high-risk surgical patient*, contains some material from '*Perioperative management of the high-risk surgical patient*' by Rupert M. Pearse and Richard M. Langford. The material has been revised and updated by the current authors.

Chapter 20, *Nutrition and fluid therapy*, the author would like to thank Marcel Gatt MD FRCS, who provided some illustrations and helped with proofreading the text.

Chapter 21, *Postoperative care*, contains some material from '*Postoperative care*' by Alistair Pace and Nicholas C.M. Armitage. The material has been revised and updated by the current author.

Chapter 25, *Head injury*, contains some material from '*Head injury*' by Richard Stacey and John Leach. The material has been revised and updated by the current authors.

Chapter 34, *Sports medicine and sports injuries*, contains some material from '*Sports medicine and sports injuries*' by D.L. Back and Jay Smith. The material has been revised and updated by the current author.

Chapter 36, *Upper limb – pathology, assessment and management*, contains some material from '*Upper limb – pathology, assessment and management*' by Srinath Kamineni. The material has been revised and updated by the current authors.

Chapter 37, *Hip and knee*, contains some material from '*Hip and knee*' by Vikas Khanduja and Richard N. Villar. The material has been revised and updated by the current authors.

Chapter 38, *Foot and ankle*, contains some material from '*Foot and ankle*' by Mark Davies, Matthew C. Solan and Vikas Khanduja. The material has been revised and updated by the current author.

Chapter 41, *Paediatric orthopaedics*, contains some material from '*Paediatric orthopaedics*' by the current author and Joanna Hicks, which has been revised and updated for this edition.

Chapter 43, *Elective neurosurgery*, contains some material from '*Elective Neurosurgery*' by John Leach and Richard Kerr. The material has been revised and updated by the current authors.

Chapter 44, *The eye and orbit*, contains some material from '*The eye and orbit*' by Jonathan D. Jagger and Hugo W.A. Henderson. The material has been revised and updated by the current author.

Chapter 48, *The pharynx, larynx and neck*, contains some material from '*The pharynx, larynx and neck*' by Jonathan D. Jagger and Hugo W.A. Henderson. The material has been revised and updated by the current author.

Chapter 52, *The adrenal glands and other abdominal endocrine disorders*, contains some material from '*Adrenal glands and other endocrine disorders*' by Matthias Rothmund. The material has been revised and updated by the current author.

Chapter 54, *Cardiac surgery*, contains some material from '*Cardiac surgery*' by Jonathan Anderson and Ian Hunt. The material has been revised and updated by the current authors.

Chapter 55, *The thorax*, contains some material from '*The thorax*' by Tom Treasure. The material has been revised and updated by the current authors.

Chapter 56, *Arterial disorders*, contains some material from '*Arterial disorders*' by John A. Murie. The material has been revised and updated by the current author.

Chapter 57, *Venous disorders*, contains some material from '*Venous disorders*' by Kevin Burnand. The material has been revised and updated by the current authors.

Chapter 58, *Lymphatic disorders*, contains some material from '*Lymphatic disorders*' by Shervanthi Homer-Vanniasinkam and Andrew Bradbury. The material has been revised and updated by the current authors.

Chapter 59, *History and examination of the abdomen*, contains some material from '*History and examination of the abdomen*' by Simon Paterson-Brown. The material has been revised and updated by the current authors.

Chapter 60, *Abdominal wall, hernia and umbilicus*, contains some material from '*Hernias, umbilicus and abdominal wall*' by Andrew N. Kingsnorth, Giorgi Giorgobiani and David H. Bennett. The material has been revised and updated by the current authors.

Chapter 61, *The peritoneum, omentum, mesentery and retroperitoneal space*, contains some material from '*The peritoneum, omentum, mesentery and retroperitoneal space*' by Jerry Thompson. The material has been revised and updated by the current author.

Chapter 65, *The liver*, contains some material from '*The liver*' by Brian R. Davidson. The material has been revised and updated by the current authors.

Chapter 69, *The small and large intestines*, contains some material from '*The small and large intestines*' by Neil J. McC Mortensen and Shazad Ashraf. The material has been revised and updated by the current authors.

Chapter 70, *Intestinal obstruction*, contains some material from '*Intestinal obstruction*' by Marc Christopher Winslet. The material has been revised and updated by the current author.

Chapter 76, *The urinary bladder*, contains some material from '*The urinary bladder*' by David E. Neal. The material has been revised and updated by the current author.

Chapter 78, *Urethra and penis*, contains some material from '*Urethra and penis*' by Christopher G. Fowler. The material has been revised and updated by the current author.

Chapter 79, *Testis and scrotum*, contains some material from '*Testis and scrotum*' by Christopher G. Fowler. The material has been revised and updated by the current author.

Sayings of the great

Both Hamilton Bailey and McNeill Love, when medical students, served as clerks to Sir Robert Hutchinson, 1871–1960, who was Consulting Physician to the London Hospital and President of the Royal College of Physicians. They never tired of quoting his ‘medical litany’, which is appropriate for all clinicians and, perhaps especially, for those who are surgically minded.

From inability to leave well alone;
From too much zeal for what is new and contempt for
what is old;
From putting knowledge before wisdom, science before
art, cleverness before common sense;
From treating patients as cases; and
From making the cure of a disease more grievous than its
endurance,
Good Lord, deliver us.

To which may be added:

The patient is the centre of the medical universe around
which all our works revolve and towards which all our
efforts trend.

J.B. Murphy, 1857–1916, Professor of Surgery,
Northwestern University, Chicago, IL, USA

To study the phenomenon of disease without books is
to sail an uncharted sea, while to study books without
patients is not to go to sea at all.

Sir William Osler, 1849–1919,
Professor of Medicine, Oxford, UK

A knowledge of healthy and diseased actions is not less
necessary to be understood than the principles of other
sciences. By and acquaintance with principles we learn
the cause of disease. Without this knowledge a man
cannot be a surgeon. ... The last part of surgery, namely
operations, is a reflection on the healing art; it is a tacit
acknowledgement of the insufficiency of surgery. It is like
an armed savage who attempts to get that by force which
a civilised man would by stratagem.

Hunter, 1728–1793, Surgeon, St George’s Hospital,
London, UK

Investigating Nature you will do well to bear ever in
mind that in every question there is the truth, whatever
our notions may be. This seems perhaps a very simple
consideration; yet it is strange how often it seems to be
disregarded. If we had nothing but pecuniary rewards and
worldly honours to look to, our profession would not be
one to be desired. But in its practice you will find it to
be attended with peculiar privileges; second to none in
intense interest and pure pleasures. It is our proud office
to tend the fleshy tabernacle of the immortal spirit, and
our path, if rightly followed, will be guided by unfettered
truth and love unfeigned. In the pursuit of this noble and
holy calling I wish you all God-speed.

Promoter’s address, Graduation in Medicine,
University of Edinburgh, August, 1876, by Lord Lister,
the Founder of Modern Surgery

Surgery has undergone many great transformations during
the past fifty years, and many are to be thanked for their
contributions – yet when we think of how many remain
to be made, it should rather stimulate our inventiveness
than fuel our vanity.

Sir Percival Pott, 1714–88, Surgeon,
St Bartholomew’s Hospital, London, UK

If you cannot make a diagnosis at least make a decision!

Sir Harry Platt, 1897–1986,

Professor of Orthopaedics, Manchester,
and President of the Royal College of Surgeons England,
London, UK

If the surgeon cuts a vessel and knows the name of that
vessel, the situation is serious; if the anaesthetist knows
the name of that vessel, the situation is irretrievable.

Maldwyn Morgan 1938–
Anaesthetist, Hammersmith Hospital, London, UK

Metabolic response to injury

LEARNING OBJECTIVES

To understand:

- Classical concepts of homeostasis
- Mediators of the metabolic response to injury
- Physiological and biochemical changes that occur during injury and recovery
- Changes in body composition that accompany surgical injury
- Avoidable factors that compound the metabolic response to injury
- Concepts behind optimal perioperative care

BASIC CONCEPTS IN HOMEOSTASIS

In the eighteenth and nineteenth centuries, a series of eminent scientists laid the foundations of our understanding of homeostasis and the response to injury. The classical concepts of homeostasis and the response to injury are:

- 'The stability of the "milieu intérieur" is the primary condition for freedom and independence of existence' (Claude Bernard); i.e. body systems act to maintain internal constancy.
- 'Homeostasis: the co-ordinated physiological process which maintains most of the steady states of the organism' (Walter Cannon); i.e. complex homeostatic responses involving the brain, nerves, heart, lungs, kidneys and spleen work to maintain body constancy.
- 'There is a circumstance attending accidental injury which does not belong to the disease, namely that the injury done, has in all cases a tendency to produce both the deposition and means of cure' (John Hunter); i.e. responses to injury are, in general, beneficial to the host and allow healing/survival.

In essence, the concept evolved that the constancy of the 'milieu intérieur' allowed for the independence of organisms, that complex homeostatic responses sought to maintain this constancy, and that within this range of responses were the elements of healing and repair. These ideas pertained to normal physiology and mild/moderate injury. In the modern era, such concepts do not account for disease evolution following major injury/sepsis or the injured patient who would have died but for artificial organ support. Such patients exemplify less of the classical homeostatic control system (signal detector–processor–effector regulated by a negative feedback loop) and more

of the 'open loop' system, whereby only with medical/surgical resolution of the primary abnormality is a return to classical homeostasis possible.

As a consequence of modern understanding of the metabolic response to injury, elective surgical practice seeks to reduce the need for a homeostatic response by minimising the primary insult (minimal access surgery and 'stress-free' perioperative care). In emergency surgery, where the presence of tissue trauma/sepsis/hypovolaemia often compounds the primary problem, there is a requirement to augment artificially homeostatic responses (resuscitation) and to close the 'open' loop by intervening to resolve the primary insult (e.g. surgical treatment of major abdominal sepsis) and provide organ support (critical care) while the patient comes back to a situation in which homeostasis can achieve a return to normality (Summary box 1.1).

Summary box 1.1

Basic concepts

- Homeostasis is the foundation of normal physiology
- 'Stress-free' perioperative care helps to preserve homeostasis following elective surgery
- Resuscitation, surgical intervention and critical care can return the severely injured patient to a situation in which homeostasis becomes possible once again

This chapter aims to review the mediators of the stress response, the physiological and biochemical pathway changes associated with surgical injury and the changes in body composition that occur following surgical injury. Emphasis is laid on why knowledge of these events is important to understand the rationale for modern 'stress-free' perioperative and critical care.

John Hunter, 1728–1793, surgeon, St George's Hospital, London, UK. He is regarded as 'The Father of Scientific Surgery'. To further his knowledge of venereal disease he inoculated himself with syphilis in 1767.

Claude Bernard, 1813–1878, Professor of Physiology, The College de France, Paris, France.

Walter Bradford Cannon, 1871–1945, Professor of Physiology, Harvard University Medical School, Boston, MA, USA.

THE GRADED NATURE OF THE INJURY RESPONSE

It is important to recognise that the response to injury is graded: the more severe the injury, the greater the response (Figure 1.1). This concept not only applies to physiological/metabolic changes but also to immunological changes/sequelae. Thus, following elective surgery of intermediate severity, there may be a transient and modest rise in temperature, heart rate, respiratory rate, energy expenditure and peripheral white cell count. Following major trauma/sepsis, these changes are accentuated, resulting in a systemic inflammatory response syndrome (SIRS), hyper-metabolism, marked catabolism, shock and even multiple organ dysfunction (MODS). It is important to recognise that genetic variability plays a key role in determining the intensity of the inflammatory response. Moreover, in certain circumstances, the severity of injury does not lead to a simple dose-dependent metabolic response, but rather leads to quantitatively different responses.

Not only is the metabolic response graded, but it also evolves with time. In particular, the immunological sequelae of major injury evolve from a proinflammatory state driven primarily by the innate immune system (macrophages, neutrophils, dendritic cells) into a compensatory anti-inflammatory response syndrome (CARS) characterised by suppressed immunity and diminished resistance to infection. In patients who develop infective complications, the latter will drive ongoing systemic inflammation, the acute phase response and continued catabolism.

Figure 1.1 Hypermetabolism and increased nitrogen excretion are closely related to the magnitude of the initial injury and show a graded response.

MEDIATORS OF THE METABOLIC RESPONSE TO INJURY

The classical neuroendocrine pathways of the stress response consist of afferent nociceptive neurones, the spinal cord, thalamus, hypothalamus and pituitary (Figure 1.2). Corticotrophin-releasing factor (CRF) released from the hypothalamus increases adrenocorticotrophic hormone (ACTH) release from the anterior pituitary. ACTH then acts on the adrenal to increase the secretion of cortisol. Hypothalamic activation of the sympathetic nervous system causes release of adrenalin and also stimulates release of glucagon. Intravenous infusion of a cocktail of these 'counter-regulatory' hormones (glucagon, glucocorticoids and catecholamines) reproduces many aspects of the metabolic response to injury. There are, however, many other players, including alterations in insulin release and sensitivity, hypersecretion of prolactin and growth hormone (GH) in the presence of low circulatory insulin-like growth factor-1 (IGF-1) and inactivation of peripheral thyroid hormones and gonadal function. Of note, GH has direct lipolytic, insulin-antagonising and proinflammatory properties (Summary box 1.2).

Summary box 1.2

Neuroendocrine response to injury/critical illness

The neuroendocrine response to severe injury/critical illness is biphasic:

- **Acute phase** characterised by an actively secreting pituitary and elevated counter-regulatory hormones (cortisol, glucagon, adrenaline). Changes are thought to be beneficial for short-term survival
- **Chronic phase** associated with hypothalamic suppression and low serum levels of the respective target organ hormones. Changes contribute to chronic wasting

The innate immune system (principally macrophages) interacts in a complex manner with the adaptive immune system (T cells, B cells) in co-generating the metabolic response to injury (Figure 1.2). Proinflammatory cytokines including interleukin-1 (IL-1), tumour necrosis factor alpha (TNF α), IL-6 and IL-8 are produced within the first 24 hours and act directly on the hypothalamus to cause pyrexia. Such cytokines also augment the hypothalamic stress response and act directly on skeletal muscle to induce proteolysis while inducing acute phase protein production in the liver. Proinflammatory cytokines also play a complex role in the development of peripheral insulin resistance. Other important proinflammatory mediators include nitric oxide ((NO) via inducible nitric oxide synthetase (iNOS)) and a variety of prostanoids (via cyclo-oxygenase-2 (Cox-2)). Changes in organ function (e.g. renal hypoperfusion/impairment) may be induced by excessive vasoconstriction via endogenous factors such as endothelin-1.

Within hours of the upregulation of proinflammatory cytokines, endogenous cytokine antagonists enter the circulation (e.g. interleukin-1 receptor antagonist (IL-1Ra) and TNF-soluble receptors (TNF-sR-55 and 75)) and act to control the proinflammatory response. A complex further series of adaptive

Figure 1.2 The integrated response to surgical injury (first 24–48 hours): there is a complex interplay between the neuroendocrine stress response and the proinflammatory cytokine response of the innate immune system.

changes includes the development of a Th2-type counterinflammatory response (regulated by IL-4, -5, -9 and -13 and transforming growth factor beta (TGFβ)) which, if accentuated and prolonged in critical illness, is characterised as the CARS and results in immunosuppression and an increased susceptibility to opportunistic (nosocomial) infection (Summary box 1.3). Within inflamed tissue the duration and magnitude of acute inflammation as well as the return to homeostasis are influenced by a group of local mediators known as specialised pro-resolving mediators (SPM) that include essential fatty acid-derived lipoxins, resolvins, protectins and maresins. These endogenous resolution agonists orchestrate the uptake and clearance of apoptotic polymorphonuclear neutrophils and microbial particles, reduce proinflammatory cytokines and lipid mediators as well as enhance the removal of cellular debris in the inflammatory milieu. Thus both at the systemic level (endogenous cytokine antagonists – see above) and at the local tissue level, the body attempts to limit/resolve inflammation driven dyshomeostasis.

Summary box 1.3

Systemic inflammatory response syndrome following major injury

- Is driven initially by proinflammatory cytokines (e.g. IL-1, IL-6 and TNFα)
- Is followed rapidly by increased plasma levels of cytokine antagonists and soluble receptors (e.g. IL-1Ra, TNF-sR)
- If prolonged or excessive may evolve into a counterinflammatory response syndrome

There are many complex interactions between the neuroendocrine, cytokine and metabolic axes. For example, although cortisol is immunosuppressive at high levels, it acts synergistically with IL-6 to promote the hepatic acute phase response. ACTH release is enhanced by proinflammatory cytokines and the noradrenergic system. The resulting rise in cortisol levels may form a weak feedback loop attempting to limit the proinflammatory stress response. Finally, hyperglycaemia may aggravate the inflammatory response via substrate overflow in the mitochondria, causing the formation of excess free oxygen radicals and also altering gene expression to enhance cytokine production.

At the molecular level, the changes that accompany systemic inflammation are extremely complex. In a recent study using network-based analysis of changes in mRNA expression in leukocytes following exposure to endotoxin, there were changes in the expression of more than 3700 genes with over half showing decreased expression and the remainder increased expression. The cell surface receptors, signalling mechanisms and transcription factors that initiate these events are also complex, but an early and important player involves the nuclear factor kappa B (NFκB)/relA family of transcription factors. A simplified model of current understanding of events within skeletal muscle is shown in Figure 1.3.

THE METABOLIC STRESS RESPONSE TO SURGERY AND TRAUMA: THE 'EBB AND FLOW' MODEL

In the natural world, if an animal is injured, it displays a characteristic response, which includes immobility, anorexia and catabolism (Summary box 1.4).

Figure 1.3 The major catabolic and anabolic signalling pathways involved in skeletal muscle homeostasis. FOXO, forkhead box sub-group O; mTOR, mammalian target of rapamycin; MyoD, myogenic differentiation factor D; NFκB, nuclear factor kappa B; PI3K, phosphatidylinositol 3-kinase; p70S6K, p70S6 kinase; TNFα, tumour necrosis factor alpha; 4E-BP-1, eukaryotic initiation translation factor 4E binding protein 1.

Summary box 1.4

Physiological response to injury

The natural response to injury includes:

- Immobility/rest
- Anorexia
- Catabolism

The changes are designed to aid survival of moderate injury in the absence of medical intervention.

In 1930, Sir David Cuthbertson divided the metabolic response to injury in humans into 'ebb' and 'flow' phases (Figure 1.4). The ebb phase begins at the time of injury and lasts for approximately 24–48 hours. It may be attenuated by proper resuscitation, but not completely abolished. The ebb phase is characterised by hypovolaemia, decreased basal metabolic rate, reduced cardiac output, hypothermia and lactic acidosis. The predominant hormones regulating the ebb phase

are catecholamines, cortisol and aldosterone (following activation of the renin–angiotensin system). The magnitude of this neuroendocrine response depends on the degree of blood loss and the stimulation of somatic afferent nerves at the site of injury. The main physiological role of the ebb phase is to conserve both circulating volume and energy stores for recovery and repair.

Following resuscitation, the ebb phase evolves into a hypermetabolic flow phase, which corresponds to SIRS. This phase involves the mobilisation of body energy stores for recovery and repair, and the subsequent replacement of lost or damaged tissue. It is characterised by tissue oedema (from vasodilatation and increased capillary leakage), increased basal metabolic rate (hypermetabolism), increased cardiac output, raised body temperature, leukocytosis, increased oxygen consumption and increased gluconeogenesis. The flow phase may be subdivided into an initial catabolic phase, lasting approximately 3–10 days, followed by an anabolic phase, which may last for weeks if extensive recovery and repair are required following serious injury. During the catabolic phase, the increased production of counter-regulatory hormones (including catecholamines, cortisol, insulin and glucagon) and inflammatory cytokines (e.g. IL-1, IL-6 and TNFα) results in significant fat and protein mobilisation, leading to significant weight loss and increased urinary nitrogen excretion. The increased production of insulin at this time is associated with significant insulin resistance and, therefore, injured patients often exhibit poor glycaemic control. The combination of pronounced or prolonged catabolism in association with insulin resistance places patients within this phase at increased risk of complications, particularly infectious and cardiovascular. Obviously, the development of complications will further aggravate the neuroendocrine and inflammatory stress responses, thus creating a vicious catabolic cycle (Summary box 1.5).

Figure 1.4 Phases of the physiological response to injury (after Cuthbertson 1930).

Summary box 1.5**Purpose of neuroendocrine changes following injury**

The constellation of neuroendocrine changes following injury acts to:

- Provide essential substrates for survival
- Postpone anabolism
- Optimise host defence

These changes may be helpful in the short term, but may be harmful in the long term, especially to the severely injured patient who would otherwise not have survived without medical intervention.

Summary box 1.6**Hypermetabolism**

Hypermetabolism following injury:

- Is mainly caused by an acceleration of energy-dependent metabolic cycles
- Is limited in modern practice on account of elements of routine critical care

KEY CATABOLIC ELEMENTS OF THE FLOW PHASE OF THE METABOLIC STRESS RESPONSE

There are several key elements of the flow phase that largely determine the extent of catabolism and thus govern the metabolic and nutritional care of the surgical patient. It must be remembered that, during the response to injury, not all tissues are catabolic. Indeed, the essence of this coordinated response is to allow the body to reprioritise limited resources away from peripheral tissues (muscle, adipose tissue, skin) and towards key viscera (liver, immune system) and the wound (Figure 1.5).

Hypermetabolism

The majority of trauma patients (except possibly those with extensive burns) demonstrate energy expenditures approximately 15–25 per cent above predicted healthy resting values. The predominant cause appears to be a complex interaction between the central control of metabolic rate and peripheral energy utilisation. In particular, central thermoregulation (caused by the proinflammatory cytokine cascade), increased sympathetic activity, abnormalities in wound circulation (ischaemic areas produce lactate, which must be metabolised by the adenosine triphosphate (ATP)-consuming hepatic Cori cycle; hyperaemic areas cause an increase in cardiac output), increased protein turnover and nutritional support may all increase patient energy expenditure. Theoretically, patient energy expenditure could rise even higher than observed levels following surgery or trauma, but several features of standard intensive care (including bed rest, paralysis, ventilation and external temperature

regulation) counteract the hypermetabolic driving forces of the stress response. Furthermore, the skeletal muscle wasting experienced by patients with prolonged catabolism actually limits the volume of metabolically active tissue (Summary box 1.6; see below).

Alterations in skeletal muscle protein metabolism

Muscle protein is continually synthesised and broken down with a turnover rate in humans of 1–2 per cent per day, and with a greater amplitude of changes in protein synthesis (\pm two-fold) than breakdown (\pm 0.25-fold) during the diurnal cycle. Under normal circumstances, synthesis equals breakdown and muscle bulk remains constant. Physiological stimuli that promote net muscle protein accretion include feeding (especially extracellular amino acid concentration) and exercise. Paradoxically, during exercise, skeletal muscle protein synthesis is depressed, but it increases again during rest and feeding.

During the catabolic phase of the stress response, muscle wasting occurs as a result of an increase in muscle protein degradation (via enzymatic pathways), coupled with a decrease in muscle protein synthesis. The major site of protein loss is peripheral skeletal muscle, although nitrogen losses also occur in the respiratory muscles (predisposing the patient to hypoventilation and chest infections) and in the gut (reducing gut motility). Cardiac muscle appears to be mostly spared. Under extreme conditions of catabolism (e.g. major sepsis), urinary nitrogen losses can reach 14–20 g/day; this is equivalent to the loss of 500 g of skeletal muscle per day. It is remarkable that muscle catabolism cannot be inhibited fully by providing artificial nutritional support as long as the stress response continues. Indeed, in critical care, it is now recognised that 'hyperalimentation' represents a metabolic stress in itself, and that nutritional support should be at a modest level to attenuate rather than replace energy and protein losses.

Figure 1.5 During the metabolic response to injury, the body reprioritises protein metabolism away from peripheral tissues and towards key central tissues such as the liver, immune system and wound. One of the main reasons why the reutilisation of amino acids derived from muscle proteolysis leads to net catabolism is that the increased glutamine and alanine efflux from muscle is derived, in part, from the irreversible degradation of branched chain amino acids. Ala, alanine; Gln, glutamine.

Figure 1.6 The intercellular effector mechanisms involved in degrading myofibrillar protein into free amino acids. The ubiquitin–proteasome pathway is a complex multistep process, which requires adenosine triphosphate and results in the tagging of specific proteins with ubiquitin for degradation of proteasome. E1, ubiquitin-activating enzyme; E2, ubiquitin-conjugating enzyme; E3, ubiquitin ligase.

The predominant mechanism involved in the wasting of skeletal muscle is the ATP-dependent ubiquitin–proteasome pathway (Figure 1.6), although the lysosomal cathepsins and the calcium–calpain pathway play facilitatory and accessory roles.

Clinically, a patient with skeletal muscle wasting will experience asthenia, increased fatigue, reduced functional ability, decreased quality of life and an increased risk of morbidity and mortality. In critically ill patients, muscle weakness may be further worsened by the development of critical illness myopathy, a multifactorial condition that is associated with impaired excitation–contraction coupling at the level of the sarcolemma and the sarcoplasmic reticulum membrane (Summary box 1.7).

Summary box 1.7

Skeletal muscle wasting

- Provides amino acids for the metabolic support of central organs/tissues
- Is mediated at a molecular level mainly by activation of the ubiquitin–proteasome pathway
- Can result in immobility and contribute to hypostatic pneumonia and death if prolonged and excessive

Alterations in hepatic protein metabolism: the acute phase protein response

The liver and skeletal muscle together account for >50 per cent of daily body protein turnover. Skeletal muscle has a large mass but a low turnover rate (1–2 per cent per day), whereas the liver has a relatively small mass (1.5 kg) but a much higher protein turnover rate (10–20 per cent per day). Hepatic protein synthesis is divided roughly 50:50 between renewal of structural

proteins and synthesis of export proteins. Albumin is the major export protein produced by the liver and is renewed at the rate of about 10 per cent per day. The transcapillary escape rate (TER) of albumin is about ten times the rate of synthesis, and short-term changes in albumin concentration are most probably due to increased vascular permeability. Albumin TER may be increased three-fold following major injury/sepsis.

In response to inflammatory conditions, including surgery, trauma, sepsis, cancer or autoimmune conditions, circulating peripheral blood mononuclear cells secrete a range of pro-inflammatory cytokines, including IL-1, IL-6 and TNF α . These cytokines, in particular IL-6, promote the hepatic synthesis of positive acute phase proteins, e.g. fibrinogen and C-reactive protein (CRP). The acute phase protein response (APPR) represents a ‘double-edged sword’ for surgical patients as it provides proteins important for recovery and repair, but only at the expense of valuable lean tissue and energy reserves.

In contrast to the positive acute phase reactants, the plasma concentrations of other liver export proteins (the negative acute phase reactants) fall acutely following injury, e.g. albumin. However, rather than represent a reduced hepatic synthesis rate, the fall in plasma concentration of negative acute phase reactants is thought principally to reflect increased transcapillary escape, secondary to an increase in microvascular permeability (see above). Thus, increased hepatic synthesis of positive acute phase reactants is not compensated for by reduced synthesis of negative reactants (Summary box 1.8).

Carl Ferdinand Cori, 1896–1984, Professor of Pharmacology, and later of Biochemistry, Washington University Medical School, St Louis, MI, USA and his wife **Gerty Theresa Cori**, 1896–1957, who was also Professor of Biochemistry at the Washington University Medical School. In 1947 the Coris were awarded a share of the Nobel Prize for Physiology or Medicine ‘for their discovery of how glycogen is catalytically converted’.

Summary box 1.8**Hepatic acute phase response**

The hepatic acute phase response represents a reprioritisation of body protein metabolism towards the liver and is characterised by:

- **Positive** reactants (e.g. CRP): plasma concentration ↑
- **Negative** reactants (e.g. albumin): plasma concentration ↓

Insulin resistance

Following surgery or trauma, postoperative hyperglycaemia develops as a result of increased glucose production combined with decreased glucose uptake in peripheral tissues. Decreased glucose uptake is a result of insulin resistance which is transiently induced within the stressed patient. Suggested mechanisms for this phenomenon include the action of proinflammatory cytokines and the decreased responsiveness of insulin-regulated glucose transporter proteins. The degree of insulin resistance is proportional to the magnitude of the injurious process. Following routine upper abdominal surgery, insulin resistance may persist for approximately 2 weeks.

Postoperative patients with insulin resistance behave in a similar manner to individuals with type II diabetes mellitus. The mainstay of management of insulin resistance is intravenous insulin infusion. Insulin infusions may be used in either an intensive approach (i.e. sliding scales are manipulated to normalise the blood glucose level) or a conservative approach (i.e. insulin is administered when the blood glucose level exceeds a defined limit and discontinued when the level falls). Studies of postoperatively ventilated patients in the intensive care unit (ICU) have suggested that maintenance of normal glucose levels using intensive insulin therapy can significantly reduce both morbidity and mortality. Furthermore, intensive insulin therapy is superior to conservative insulin approaches in reducing morbidity rates. However, the mortality benefit of intensive insulin therapy over a more conservative approach has not been proven conclusively. The observed benefits of insulin therapy are probably simply as a result of maintenance of normoglycaemia, but the glycaemia-independent actions of insulin may also exert minor, organ-specific effects (e.g. promotion of myocardial systolic function).

CHANGES IN BODY COMPOSITION FOLLOWING INJURY

The average 70-kg male can be considered to consist of fat (13 kg) and fat-free mass (or lean body mass: 57 kg). In such an individual, the lean tissue is composed primarily of protein (12 kg), water (42 kg) and minerals (3 kg) (Figure 1.7). The protein mass can be considered as two basic compartments, skeletal muscle (4 kg) and non-skeletal muscle (8 kg), which includes the visceral protein mass. The water mass (42 litres) is divided into intercellular (28 litres) and extracellular (14 litres) spaces. Most of the mineral mass is contained in the bony skeleton.

The main labile energy reserve in the body is fat, and the main labile protein reserve is skeletal muscle. While fat mass can be reduced without major detriment to function, loss of protein mass results not only in skeletal muscle wasting, but

Figure 1.7 The chemical body composition of a normal 70-kg male. FFM, fat-free mass; LBM, lean body mass.

also depletion of visceral protein status. Within lean tissue, each 1 g of nitrogen is contained within 6.25 g of protein, which is contained in approximately 36 g of wet weight tissue. Thus, the loss of 1 g of nitrogen in urine is equivalent to the breakdown of 36 g of wet weight lean tissue. Protein turnover in the whole body is of the order of 150–200 g per day. A normal human ingests about 70–100 g protein per day, which is metabolised and excreted in urine as ammonia and urea (i.e. approximately 14 g N/day). During total starvation, urinary loss of nitrogen is rapidly attenuated by a series of adaptive changes. Loss of body weight follows a similar course (Figure 1.8), thus accounting for the survival of hunger strikers for a period of 50–60 days. Following major injury, and particularly in the presence of ongoing septic complications, this adaptive change fails to occur, and there is a state of 'autocannibalism', resulting in continuing urinary nitrogen losses of 10–20 g N/day (equivalent to 500 g of wet weight lean tissue per day). As with total starvation, once loss of body protein mass has reached 30–40 per cent of the total, survival is unlikely.

Critically ill patients admitted to the ICU with severe sepsis or major blunt trauma undergo massive changes in body composition (Figure 1.8). Body weight increases immediately on resuscitation with an expansion of extracellular water by 6–10 litres within 24 hours. Thereafter, even with optimal metabolic care and nutritional support, total body protein will diminish by 15 per cent in the next 10 days, and body weight will reach negative balance as the expansion of the extracellular space resolves. In marked contrast, it is now possible to maintain body weight and nitrogen equilibrium following major elective surgery. This can be achieved by blocking the neuroendocrine stress response with epidural analgesia and providing early enteral feeding. Moreover, the early fluid retention phase can be avoided by careful intraoperative management of fluid balance, with avoidance of excessive administration of intravenous saline (Summary box 1.9).

Figure 1.8 Changes in body weight that occur in serious sepsis, after uncomplicated surgery and in total starvation.

Summary box 1.9

Changes in body composition following major surgery/critical illness

- Catabolism leads to a **decrease** in fat mass and skeletal muscle mass
- Body weight may paradoxically **increase** because of expansion of extracellular fluid space

AVOIDABLE FACTORS THAT COMPOUND THE RESPONSE TO INJURY

As noted previously, the main features of the metabolic response are initiated by the immune system, cardiovascular system, sympathetic nervous system, ascending reticular formation and limbic system. However, the metabolic stress response may be further exacerbated by anaesthesia, dehydration, starvation (including preoperative fasting), sepsis, acute medical illness or even severe psychological stress (Figure 1.9). Attempts to limit or control these factors can be beneficial to the patient (Summary box 1.10).

Summary box 1.10

Avoidable factors that compound the response to injury

- Continuing haemorrhage
- Hypothermia
- Tissue oedema
- Tissue underperfusion
- Starvation
- Immobility

Volume loss

During simple haemorrhage, pressor receptors in the carotid artery and aortic arch, and volume receptors in the wall of the

left atrium, initiate afferent nerve input to the central nervous system (CNS), resulting in the release of both aldosterone and antidiuretic hormone (ADH). Pain can also stimulate ADH release. ADH acts directly on the kidney to cause fluid retention. Decreased pulse pressure stimulates the juxtaglomerular apparatus in the kidney and directly activates the renin–angiotensin system, which in turn increases aldosterone release.

Aldosterone causes the renal tubule to reabsorb sodium (and consequently also conserve water). ACTH release also augments the aldosterone response. The net effects of ADH and aldosterone result in the natural oliguria observed after surgery and conservation of sodium and water in the extracellular space. The tendency towards water and salt retention is exacerbated by resuscitation with saline-rich fluids. Salt and water retention can result in not only peripheral oedema, but also visceral oedema (e.g. stomach). Such visceral oedema has been associated with reduced gastric emptying, delayed resumption of food intake and prolonged hospital stay. Careful limitation of intraoperative administration of colloids and crystalloids (e.g. Hartmann's solution) so that there is no net weight gain following elective surgery has been proven to reduce postoperative complications and length of stay.

Hypothermia

Hypothermia results in increased elaboration of adrenal steroids and catecholamines. When compared with normothermic controls, even mild hypothermia results in a two- to three-fold increase in postoperative cardiac arrhythmias and increased catabolism. Randomised trials have shown that maintaining normothermia by an upper body forced-air heating cover reduces wound infections, cardiac complications and bleeding and transfusion requirements.

Tissue oedema

During systemic inflammation, fluid, plasma proteins, leukocytes, macrophages and electrolytes leave the vascular space and accumulate in the tissues. This can diminish the alveolar diffusion of oxygen and may lead to reduced renal function. Increased capillary leak is mediated by a wide variety of mediators including cytokines, prostanoids, bradykinin and nitric oxide. Vasodilatation implies that intravascular volume

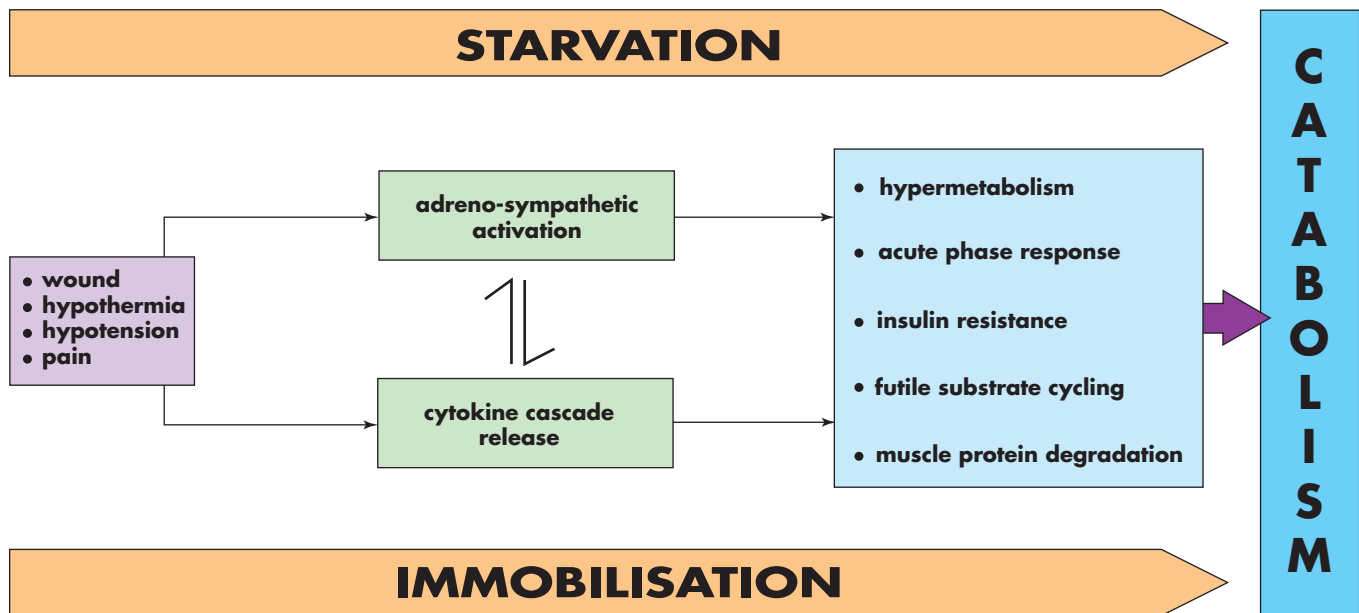

Figure 1.9 Factors that exacerbate the metabolic response to surgical injury include hypothermia, controlled pain, starvation, immobilisation, sepsis and medical complications

decreases, which induces shock if inadequate resuscitation is not undertaken. Meanwhile, intracellular volume decreases, and this provides part of the volume necessary to replenish intravascular and extravascular extracellular volume.

Systemic inflammation and tissue underperfusion

The vascular endothelium controls vasomotor tone and microvascular flow, and regulates trafficking of nutrients and biologically active molecules. When endothelial activation is excessive, compromised microcirculation and subsequent cellular hypoxia contribute to the risk of organ failure. Maintaining normoglycaemia with insulin infusion during critical illness has been proposed to protect the endothelium, probably in part, via inhibition of excessive iNOS-induced NO release, and thereby contribute to the prevention of organ failure and death. Administration of activated protein C to critically ill patients has been shown to reduce organ failure and death and is thought to act, in part, via preservation of the microcirculation in vital organs.

Starvation

During starvation, the body is faced with an obligate need to generate glucose to sustain cerebral energy metabolism (100 g of glucose per day). This is achieved in the first 24 hours by mobilising glycogen stores and thereafter by hepatic gluconeogenesis from amino acids, glycerol and lactate. The energy metabolism of other tissues is sustained by mobilising fat from adipose tissue. Such fat mobilisation is mainly dependent on a fall in circulating insulin levels. Eventually, accelerated loss of lean tissue (the main source of amino acids for hepatic gluconeogenesis) is reduced as a result of the liver converting free fatty acids into ketone bodies, which can serve as a substitute for glucose for

cerebral energy metabolism. Provision of 2 litres of intravenous 5 per cent dextrose as intravenous fluids for surgical patients who are fasted provides 100 g of glucose per day and has a significant protein-sparing effect. Avoiding unnecessary fasting in the first instance and early oral/enteral/parenteral nutrition form the platform for avoiding loss of body mass as a result of the varying degrees of starvation observed in surgical patients. Modern guidelines on fasting prior to anaesthesia allow intake of clear fluids up to 2 hours before surgery. Administration of a carbohydrate drink at this time reduces perioperative anxiety and thirst and decreases postoperative insulin resistance.

Immobility

Immobility has long been recognised as a potent stimulus for inducing muscle wasting. Inactivity impairs the normal meal-derived amino acid stimulation of protein synthesis in skeletal muscle. Avoidance of unnecessary bed rest and active early mobilisation are essential measures to avoid muscle wasting as a consequence of immobility.

CONCEPTS BEHIND OPTIMAL PERIOPERATIVE CARE

Current understanding of the metabolic response to surgical injury and the mediators involved has led to a reappraisal of traditional perioperative care. There is now a strong scientific rationale for avoiding unmodulated exposure to stress, prolonged fasting and excessive administration of intravenous (saline) fluids (Figure 1.10). The widespread adoption of minimal access (laparoscopic) surgery is a key change in surgical practice that can reduce the magnitude of surgical injury and enhance the rate of patients' return to homeostasis and recovery. It is also impor-

Figure 1.10 Enhanced recovery after surgery (ERAS) programmes can be modulated by multimodal enhanced recovery programmes (optimal nutritional and metabolic care to minimise the stress response).

tant to realise that modulating the stress/inflammatory response at the time of surgery may have long-term sequelae over periods of months or longer. For example, β -blockers and statins have recently been shown to improve long-term survival after major surgery. It has been suggested that these effects may be due to suppression of innate immunity at the time of surgery. Equally, the use of epidural analgesia to reduce pain, block the cortisol stress response and attenuate postoperative insulin resistance may, via effects on the body's protein economy, favourably affect many of the patient-centred outcomes that are important to postoperative recovery but have largely been unmeasured to date, such as functional capacity, vitality and ability to return to work (Summary box 1.11).

Summary box 1.11

A proactive approach to prevent unnecessary aspects of the surgical stress response

- Minimal access techniques
- Blockade of afferent painful stimuli (e.g. epidural analgesia)
- Minimal periods of starvation
- Early mobilisation

Shock and blood transfusion

LEARNING OBJECTIVES

To understand:

- The pathophysiology of shock and ischaemia–reperfusion injury
- The different patterns of shock and the principles and priorities of resuscitation
- Appropriate monitoring and end points of resuscitation
- Use of blood and blood products, the benefits and risks of blood transfusion

INTRODUCTION

Shock is the most common and therefore the most important cause of death of surgical patients. Death may occur rapidly due to a profound state of shock, or be delayed due to the consequences of organ ischaemia and reperfusion injury. It is important therefore that every surgeon understands the pathophysiology, diagnosis and priorities in management of shock and haemorrhage.

SHOCK

Shock is a systemic state of low tissue perfusion which is inadequate for normal cellular respiration. With insufficient delivery of oxygen and glucose, cells switch from aerobic to anaerobic metabolism. If perfusion is not restored in a timely fashion, cell death ensues.

Pathophysiology

Cellular

As perfusion to the tissues is reduced, cells are deprived of oxygen and must switch from aerobic to anaerobic metabolism. The product of anaerobic respiration is not carbon dioxide but lactic acid. When enough tissue is underperfused, the accumulation of lactic acid in the blood produces a systemic metabolic acidosis.

As glucose within cells is exhausted, anaerobic respiration ceases and there is failure of sodium/potassium pumps in the cell membrane and intracellular organelles. Intracellular lysosomes release autodigestive enzymes and cell lysis ensues. Intracellular contents, including potassium are released into the blood stream.

Microvascular

As tissue ischaemia progresses, changes in the local milieu result in activation of the immune and coagulation systems. Hypoxia and acidosis activate complement and prime neutrophils, resulting in the generation of oxygen free radicals and cytokine

release. These mechanisms lead to injury of the capillary endothelial cells. These, in turn, further activate the immune and coagulation systems. Damaged endothelium loses its integrity and becomes 'leaky'. Spaces between endothelial cells allow fluid to leak out and tissue oedema ensues, exacerbating cellular hypoxia.

Systemic

Cardiovascular

As preload and afterload decrease, there is a compensatory baroreceptor response resulting in increased sympathetic activity and release of catecholamines into the circulation. This results in tachycardia and systemic vasoconstriction (except in sepsis – see below).

Respiratory

The metabolic acidosis and increased sympathetic response result in an increased respiratory rate and minute ventilation to increase the excretion of carbon dioxide (and so produce a compensatory respiratory alkalosis).

Renal

Decreased perfusion pressure in the kidney leads to reduced filtration at the glomerulus and a decreased urine output. The renin–angiotensin–aldosterone axis is stimulated, resulting in further vasoconstriction and increased sodium and water reabsorption by the kidney.

Endocrine

As well as activation of the adrenal and renin–angiotensin systems, vasopressin (antidiuretic hormone) is released from the hypothalamus in response to decreased preload and results in vasoconstriction and resorption of water in the renal collecting system. Cortisol is also released from the adrenal cortex contributing to the sodium and water resorption and sensitizing the cells to catecholamines.

Table 2.1 Cardiovascular and metabolic characteristics of shock.

	Hypovolaemia	Cardiogenic	Obstructive	Distributive
Cardiac output	Low	Low	Low	High
Vascular resistance	High	High	High	Low
Venous pressure	Low	High	High	Low
Mixed venous saturation	Low	Low	Low	High
Base deficit	High	High	High	High

Ischaemia–reperfusion syndrome

During the period of systemic hypoperfusion, cellular and organ damage progresses due to the direct effects of tissue hypoxia and local activation of inflammation. Further injury occurs once normal circulation is restored to these tissues. The acid and potassium load that has built up can lead to direct myocardial depression, vascular dilatation and further hypotension. The cellular and humoral elements activated by the hypoxia (complement, neutrophils, microvascular thrombi) are flushed back into the circulation where they cause further endothelial injury to organs such as the lungs and the kidneys. This leads to acute lung injury, acute renal injury, multiple organ failure and death. Reperfusion injury can currently only be attenuated by reducing the extent and duration of tissue hypoperfusion.

Classification of shock

There are numerous ways to classify shock, but the most common and most clinically applicable is one based on the initiating mechanism (Summary box 2.1).

All states are characterised by systemic tissue hypoperfusion and different states may coexist within the same patient.

Summary box 2.1

Classification of shock

- Hypovolaemic shock
- Cardiogenic shock
- Obstructive shock
- Distributive shock
- Endocrine shock

Hypovolaemic shock

Hypovolaemic shock is due to a reduced circulating volume. Hypovolaemia may be due to haemorrhagic or non-haemorrhagic causes. Non-haemorrhagic causes include poor fluid intake (dehydration), excessive fluid loss due to vomiting, diarrhoea, urinary loss (eg. diabetes), evaporation, or 'third-spacing' where fluid is lost into the gastrointestinal tract and interstitial spaces, as for example in bowel obstruction or pancreatitis.

Hypovolaemia is probably the most common form of shock, and to some degree is a component of all other forms of shock. Absolute or relative hypovolaemia must be excluded or treated in the management of the shocked state, regardless of cause.

Cardiogenic shock

Cardiogenic shock is due to primary failure of the heart to pump blood to the tissues. Causes of cardiogenic shock include myocardial infarction, cardiac dysrhythmias, valvular heart disease, blunt myocardial injury and cardiomyopathy. Cardiac insufficiency may also be due to myocardial depression due to endogenous factors (e.g. bacterial and humoral agents released in sepsis) or exogenous factors, such as pharmaceutical agents or drug abuse. Evidence of venous hypertension with pulmonary or systemic oedema may coexist with the classical signs of shock.

Obstructive shock

In obstructive shock there is a reduction in preload due to mechanical obstruction of cardiac filling. Common causes of obstructive shock include cardiac tamponade, tension pneumothorax, massive pulmonary embolus or air embolus. In each case, there is reduced filling of the left and/or right sides of the heart leading to reduced preload and a fall in cardiac output.

Distributive shock

Distributive shock describes the pattern of cardiovascular responses characterising a variety of conditions, including septic shock, anaphylaxis and spinal cord injury. Inadequate organ perfusion is accompanied by vascular dilatation with hypotension, low systemic vascular resistance, inadequate afterload and a resulting abnormally high cardiac output.

In anaphylaxis, vasodilatation is due to histamine release, while in high spinal cord injury there is failure of sympathetic outflow and adequate vascular tone (neurogenic shock). The cause in sepsis is less clear but is related to the release of bacterial products (endotoxin) and the activation of cellular and humoral components of the immune system. There is maldistribution of blood flow at a microvascular level with arteriovenous shunting and dysfunction of cellular utilization of oxygen.

In the later phases of septic shock there is hypovolaemia from fluid loss into interstitial spaces and there may be concomitant myocardial depression, complicating the clinical picture (Table 2.1).

Endocrine shock

Endocrine shock may present as a combination of hypovolaemic, cardiogenic or distributive shock. Causes of endocrine shock include hypo- and hyperthyroidism and adrenal insufficiency. Hypothyroidism causes a shock state similar to that of neuro-

Table 2.2 Clinical features of shock.

	Compensated	Mild	Moderate	Severe
Lactic acidosis	+	++	++	+++
Urine output	Normal	Normal	Reduced	Anuric
Conscious level	Normal	Mild anxiety	Drowsy	Comatose
Respiratory rate	Normal	Increased	Increased	Laboured
Pulse rate	Mild increase	Increased	Increased	Increased
Blood pressure	Normal	Normal	Mild hypotension	Severe hypotension

genic shock due to disordered vascular and cardiac responsiveness to circulating catecholamines. Cardiac output falls due to low inotropy and bradycardia. There may also be an associated cardiomyopathy. Thyrotoxicosis may cause a high-output cardiac failure.

Adrenal insufficiency leads to shock due to hypovolaemia and a poor response to circulating and exogenous catecholamines. Adrenal insufficiency may be due to pre-existing Addison's disease or be a relative insufficiency due to a pathological disease state, such as systemic sepsis.

Severity of shock

Compensated shock

As shock progresses, the body's cardiovascular and endocrine compensatory responses reduce flow to non-essential organs to preserve preload and flow to the lungs and brain. In compensated shock, there is adequate compensation to maintain central blood volume and preserve flow to the kidneys, lungs and brain. Apart from a tachycardia and cool peripheries (vasoconstriction, circulating catecholamines), there may be no other clinical signs of hypovolaemia.

However, this cardiovascular state is only maintained by reducing perfusion to the skin, muscle and gastrointestinal tract. There is a systemic metabolic acidosis and activation of humoral and cellular elements within the underperfused organs. Although clinically occult, this state will lead to multiple organ failure and death if prolonged due to the ischaemia-reperfusion effect described above under Ischaemia-reperfusion syndrome. Patients with occult hypoperfusion (metabolic acidosis despite normal urine output and cardiorespiratory vital signs) for more than 12 hours have a significantly higher mortality, infection rate and incidence of multiple organ failure (see below under Multiple organ failure).

Decompensation

Further loss of circulating volume overloads the body's compensatory mechanisms and there is progressive renal, respiratory and cardiovascular decompensation. In general, loss of around 15 per cent of the circulating blood volume is within normal compensatory mechanisms. Blood pressure is usually well maintained and only falls after 30–40 per cent of circulating volume has been lost.

Mild shock

Initially there is tachycardia, tachypnoea, a mild reduction in

urine output and the patient may exhibit mild anxiety. Blood pressure is maintained although there is a decrease in pulse pressure. The peripheries are cool and sweaty with prolonged capillary refill times (except in septic distributive shock).

Moderate shock

As shock progresses, renal compensatory mechanisms fail, renal perfusion falls and urine output dips below 0.5 mL/kg per hour. There is further tachycardia, and now the blood pressure starts to fall. Patients become drowsy and mildly confused.

Severe shock

In severe shock, there is profound tachycardia and hypotension. Urine output falls to zero and patients are unconscious with laboured respiration.

Pitfalls

The classic cardiovascular responses described (Table 2.2) are not seen in every patient. It is important to recognise the limitations of the clinical examination and to recognise patients who are in shock despite the absence of classic signs.

Capillary refill

Most patients in hypovolaemic shock will have cool, pale peripheries, with prolonged capillary refill times. However, the actual capillary refill time varies so much in adults that it is not a specific marker of whether a patient is shocked, and patients with short capillary refill times may be in the early stages of shock. In distributive (septic) shock, the peripheries will be warm and capillary refill will be brisk, despite profound shock.

Tachycardia

Tachycardia may not always accompany shock. Patients who are on beta-blockers or who have implanted pacemakers are unable to mount a tachycardia. A pulse rate of 80 in a fit young adult who normally has a pulse rate of 50 is very abnormal. Furthermore, in some young patients with penetrating trauma, where there is haemorrhage but little tissue damage, there may be a paradoxical bradycardia rather than tachycardia accompanying the shocked state.

Blood pressure

It is important to recognise that hypotension is one of the last signs of shock. Children and fit young adults are able to maintain blood pressure until the final stages of shock by dramatic

increases in stroke volume and peripheral vasoconstriction. These patients can be in profound shock with a normal blood pressure.

Elderly patients who are normally hypertensive may present with a 'normal' blood pressure for the general population but be hypovolaemic and hypotensive relative to their usual blood pressure. Beta-blockers or other medications may prevent a tachycardic response. The diagnosis of shock may be difficult unless one is alert to these pitfalls.

Consequences

Unresuscitatable shock

Patients who are in profound shock for a prolonged period of time become 'unresuscitatable'. Cell death follows from cellular ischaemia and the ability of the body to compensate is lost. There is myocardial depression and loss of responsiveness to fluid or inotropic therapy. Peripherally there is loss of the ability to maintain systemic vascular resistance and further hypotension ensues. The peripheries no longer respond appropriately to vasoconstrictor agents. Death is the inevitable result.

This stage of shock is the combined result of the severity of the insult and delayed, inadequate or inappropriate resuscitation in the earlier stages of shock. Conversely, when patients present in this late stage, and have minimal responses to maximal therapy, it is important that the futility of treatment is recognised and valuable resources are not wasted.

Multiple organ failure

As techniques of resuscitation have improved, more and more patients are surviving shock. Where intervention is timely and the period of shock is limited, patients may make a rapid, uncomplicated recovery. However, the result of prolonged systemic ischaemia and reperfusion injury is end-organ damage and multiple organ failure.

Multiple organ failure is defined as two or more failed organ systems (Summary box 2.2).

Summary box 2.2

Effects of organ failure

- Lung: Acute respiratory distress syndrome
- Kidney: Acute liver insufficiency
- Clotting: Coagulopathy
- Cardiac: Cardiovascular failure

There is no specific treatment for multiple organ failure. Management is supporting of organ systems with ventilation, cardiovascular support and haemofiltration/dialysis until there is recovery of organ function. Multiple organ failure currently carries a mortality of 60 per cent; thus prevention is vital by early aggressive identification and reversal of shock.

RESUSCITATION

Immediate resuscitation manoeuvres for patients presenting in shock are to ensure a patent airway and adequate oxygenation

and ventilation. Once 'airway' and 'breathing' are assessed and controlled, attention is directed to cardiovascular resuscitation.

Conduct of resuscitation

Resuscitation should not be delayed in order to definitively diagnose the source of the shocked state. However, the timing and nature of resuscitation will depend on the type of shock and the timing and severity of the insult. Rapid clinical examination will provide adequate clues to make an appropriate first determination, even if a source of bleeding or sepsis is not immediately identifiable. If there is initial doubt about the cause of shock, it is safer to assume the cause is hypovolaemia and begin with fluid resuscitation, and then assess the response.

In patients who are actively bleeding (major trauma, aortic aneurysm rupture, gastrointestinal haemorrhage), it is counterproductive to institute high-volume fluid therapy without controlling the site of haemorrhage. Increasing blood pressure merely increases bleeding from the site while fluid therapy cools the patient and dilutes available coagulation factors. Thus operative haemorrhage control should not be delayed and resuscitation should proceed in parallel with surgery.

Conversely, a patient with bowel obstruction and hypovolaemic shock must be adequately resuscitated before undergoing surgery otherwise the additional surgical injury and hypovolaemia induced during the procedure will exacerbate the inflammatory activation and increase the incidence and severity of end-organ insult.

Fluid therapy

In all cases of shock, regardless of classification, hypovolaemia and inadequate preload must be addressed before other therapy is instituted. Administration of inotropic or chronotropic agents to an empty heart will rapidly and permanently deplete the myocardium of oxygen stores and dramatically reduce diastolic filling and therefore coronary perfusion. Patients will enter the unresuscitatable stage of shock as the myocardium becomes progressively more ischaemic and unresponsive to resuscitative attempts.

First-line therapy, therefore, is intravenous access and administration of intravenous fluids. Access should be through short, wide-bore catheters that allow rapid infusion of fluids as necessary. Long, narrow lines, such as central venous catheters, have too high a resistance to allow rapid infusion and are more appropriate for monitoring than fluid replacement therapy.

Type of fluids

There is continuing debate over which resuscitation fluid is best for the management of shock. There is no ideal resuscitation fluid, and it is more important to understand how and when to administer it. In most studies of shock resuscitation there is no overt difference in response or outcome between crystalloid solutions (normal saline, Hartmann's solution, Ringer's lactate) or colloids (albumin or commercially available products). Furthermore, there is less volume benefit to the administration

Alexis Frank Hartmann, 1898–1964, paediatrician, St Louis, MO, USA, described the solution; should not be confused with the name of Henri Albert Charles Antoine Hartmann, French surgeon, who described the operation that goes by his name.

of colloids than had previously been thought, with only 1.3 times more crystalloid than colloid administered in blinded trials. On balance, there is little evidence to support the administration of colloids, which are more expensive and have worse side-effect profiles.

Most importantly, the oxygen carrying capacity of crystalloids and colloids is zero. If blood is being lost, the ideal replacement fluid is blood, although crystalloid therapy may be required while awaiting blood products.

Hypotonic solutions (dextrose etc.) are poor volume expanders and should not be used in the treatment of shock unless the deficit is free water loss (eg. diabetes insipidus) or patients are sodium overloaded (eg. cirrhosis).

Dynamic fluid response

The shock status can be determined dynamically by the cardiovascular response to the rapid administration of a fluid bolus. In total, 250–500 mL of fluid is rapidly given (over 5–10 minutes) and the cardiovascular responses in terms of heart rate, blood pressure and central venous pressure are observed. Patients can be divided into ‘responders’, ‘transient responders’ and ‘non-responders’.

Responders have an improvement in their cardiovascular status which is sustained. These patients are not actively losing fluid but require filling to a normal volume status.

Transient responders have an improvement which then reverts to the previous state over the next 10–20 minutes. These patients have moderate ongoing fluid losses (either overt haemorrhage or further fluid shifts reducing intravascular volume).

Non-responders are severely volume depleted and are likely to have major ongoing loss of intravascular volume, usually through persistent uncontrolled haemorrhage.

Vasopressor and inotropic support

Vasopressor or inotropic therapy is not indicated as first-line therapy in hypovolaemia. As discussed above, administration of these agents in the absence of adequate preload rapidly leads to decreased coronary perfusion and depletion of myocardial oxygen reserves.

Vasopressor agents (phenylephrine, noradrenaline) are indicated in distributive shock states (sepsis, neurogenic shock) where there is peripheral vasodilatation, and a low systemic vascular resistance, leading to hypotension despite a high cardiac output. Where the vasodilatation is resistant to catecholamines (eg. absolute or relative steroid deficiency) vasopressin may be used as an alternative vasopressor.

In cardiogenic shock, or where myocardial depression complicated a shock state (eg. severe septic shock with low cardiac output), inotropic therapy may be required to increase cardiac output and therefore oxygen delivery. The inodilator dobutamine is the agent of choice.

Monitoring

The **minimum** standard for monitoring of the patient in shock is continuous heart rate and oxygen saturation monitoring, frequent non-invasive blood pressure monitoring and hourly urine output measurements. Most patients will need more aggressive invasive monitoring, including central venous pressure and invasive blood pressure monitoring (Summary box 2.3).

Summary box 2.3

Monitoring for patients in shock

Minimum

- ECG
- Pulse oximetry
- Blood pressure
- Urine output

Additional modalities

- Central venous pressure
- Invasive blood pressure
- Cardiac output
- Base deficit and serum lactate

Cardiovascular

Cardiovascular monitoring at a minimum should include continuous heart rate (ECG), oxygen saturation and pulse waveform and non-invasive blood pressure. Patients whose state of shock is not rapidly corrected with a small amount of fluid should have central venous pressure monitoring and continuous blood pressure monitoring through an arterial line.

Central venous pressure

There is no ‘normal’ central venous pressure (CVP) for a shocked patient, and reliance cannot be placed on an individual pressure measurement to assess volume status. Some patients may require a CVP of 5 cmH₂O, whereas some may require a CVP of 15 cmH₂O or higher. Further, ventricular compliance can change from minute to minute in the shocked state, and CVP is a poor reflection of end diastolic volume (preload).

CVP measurements should be assessed dynamically as response to a fluid challenge (see above). A fluid bolus (250–500 mL) is infused rapidly over 5–10 minutes.

The normal CVP response is a rise of 2–5 cmH₂O which gradually drifts back to the original level over 10–20 minutes. Patients with no change in their CVP are empty and require further fluid resuscitation. Patients with a large, sustained rise in CVP have high preload and an element of cardiac insufficiency or volume overload.

Cardiac output

Cardiac output monitoring allows not only assessment of the cardiac output but also the systemic vascular resistance and, depending on the technique used, end diastolic volume (preload) and blood volume. Use of invasive cardiac monitoring using pulmonary artery catheters is becoming less frequent as new non-invasive monitoring techniques, such as Doppler ultrasound, pulse waveform analysis and indicator dilution methods, provide similar information without many of the drawbacks of more invasive techniques.

Measurement of cardiac output, systemic vascular resistance and preload can help distinguish the types of shock present (hypovolaemia, distributive, cardiogenic), especially when they coexist. The information provided guides fluid and vasopressor therapy by providing real-time monitoring of the cardiovascular response.

Measurement of cardiac output is desirable in patients who do not respond as expected to first-line therapy, or who have evidence of cardiogenic shock or myocardial dysfunction. Early consideration should be given to instituting cardiac output monitoring on patients who require vasopressor or inotropic support.

Systemic and organ perfusion

Ultimately, the goal of treatment is to restore cellular and organ perfusion. Ideally, therefore, monitoring of organ perfusion should guide the management of shock. The best measures of organ perfusion and the best monitor of the adequacy of shock therapy remains the urine output. However, this is an hourly measure and does not give a minute-to-minute view of the shocked state. The level of consciousness is an important marker of cerebral perfusion, but brain perfusion is maintained until the very late stages of shock, and hence is a poor marker of adequacy of resuscitation (Table 2.3).

Currently, the only clinical indicators of perfusion of the gastrointestinal tract and muscular beds are the global measures of lactic acidosis (lactate and base deficit) and the mixed venous oxygen saturation.

Base deficit and lactate

Lactic acid is generated by cells undergoing anaerobic respiration. The degree of lactic acidosis, as measured by serum lactate level and/or the base deficit, is sensitive for both diagnosis of shock and monitoring the response to therapy. Patients with a base deficit over 6 mmol/L have a much higher morbidity and mortality than those with no metabolic acidosis. Furthermore, the duration of time in shock with an increased base deficit is important, even if all other vital signs have returned to normal (see occult hypoperfusion below under End points of resuscitation).

These parameters are measured from arterial blood gas analyses, and therefore the frequency of measurements is limited and they do not provide minute-to-minute data on systemic perfusion or the response to therapy. Nevertheless, the base deficit and/or lactate should be measured routinely in these patients until they have returned to normal levels.

Mixed venous oxygen saturation

The per cent saturation of oxygen returning to the heart from the body is a measure of the oxygen delivery and extraction by the tissues. Accurate measurement is via analysis of blood drawn from a long central line placed in the right atrium. Estimations can be made from blood drawn from lines in the superior vena cava, but these values will be slightly higher than those of a mixed venous sample (as there is relatively more oxygen extraction from the lower half of the body). Normal mixed venous oxygen saturation levels are 50–70 per cent. Levels below 50 per cent indicate inadequate oxygen delivery and increased oxygen extraction by the cells. This is consistent with hypovolaemic or cardiogenic shock.

High mixed venous saturations (>70 per cent) are seen in sepsis and some other forms of distributive shock. In sepsis, there is disordered utilization of oxygen at the cellular level, and arteriovenous shunting of blood at the microvascular level. Thus less oxygen is presented to the cells, and those cells cannot utilise what little oxygen is presented. Thus, venous blood has a higher oxygen concentration than normal.

Patients who are septic should therefore have mixed venous oxygen saturations above 70 per cent; below this level, they are not only in septic shock but also in hypovolaemic or cardiogenic shock. Although the S_{vO_2} level is in the 'normal' range, it is low for the septic state, and inadequate oxygen is being supplied to cells that cannot utilize oxygen appropriately. This must be corrected rapidly. Hypovolaemia should be corrected with fluid therapy, and low cardiac output due to myocardial depression or failure should be treated with inotropes (dobutamine), to achieve a mixed venous saturation greater than 70 per cent (normal for the septic state).

New methods for monitoring regional tissue perfusion and oxygenation are becoming available, the most promising of which are muscle tissue oxygen probes, near-infrared spectroscopy and sublingual capnometry. While these techniques provide information regarding perfusion of specific tissue beds, it is as yet unclear whether there are significant advantages over existing measurements of global hypoperfusion (base deficit, lactate).

Table 2.3 Monitors for organ/systemic perfusion.

	Clinical	Investigational
Systemic perfusion		Base deficit Lactate Mixed venous oxygen saturation
Organ perfusion		
Muscle	–	Near-infrared spectroscopy Tissue oxygen electrode
Gut	–	Sublingual capnometry Gut mucosal pH Laser Doppler flowmetry
Kidney	Urine output	–
Brain	Conscious level	Tissue oxygen electrode Near-infrared spectroscopy

End points of resuscitation

It is much easier to know when to start resuscitation than when to stop. Traditionally, patients have been resuscitated until they have a normal pulse, blood pressure and urine output. However, these parameters are monitoring organ systems whose blood flow is preserved until the late stages of shock. A patient therefore may be resuscitated to restore central perfusion to the brain, lungs and kidneys and yet continue to underperfuse the gut and muscle beds. Thus activation of inflammation and coagulation may be ongoing and lead to reperfusion injury when these organs are finally perfused, and ultimately multiple organ failure.

This state of normal vital signs and continued underperfusion is termed 'occult hypoperfusion'. With current monitoring techniques, it is manifested only by a persistent lactic acidosis and low mixed venous oxygen saturation. The duration patients spend in this hypoperfused state has a dramatic effect on outcome. Patients with occult hypoperfusion for more than 12 hours have two to three times the mortality of patients with a limited duration of shock.

Resuscitation algorithms directed at correcting global perfusion end points (base deficit, lactate, mixed venous oxygen saturation) rather than traditional end points have been shown to improve mortality and morbidity in high-risk surgical patients. However, it is clear that despite aggressive regimens, some patients cannot be resuscitated to normal parameters within 12 hours by fluid resuscitation alone. More research is underway to identify the pathophysiology behind this and investigate new therapeutic options.

HAEMORRHAGE

Haemorrhage must be recognised and managed aggressively to reduce the severity and duration of shock and avoid death and/or multiple organ failure. Haemorrhage is treated by arresting the bleeding – not by fluid resuscitation or blood transfusion. Although necessary as supportive measures to maintain organ perfusion, attempting to resuscitate patients who have ongoing haemorrhage will lead to physiological exhaustion (coagulopathy, acidosis and hypothermia) and subsequently death.

Pathophysiology

Haemorrhage leads to a state of hypovolaemic shock. The combination of tissue trauma and hypovolaemic shock leads to the development of an endogenous coagulopathy called acute traumatic coagulopathy (ATC). Up to 25 per cent of trauma

patients develop ATC within minutes of injury and it is associated with a four-fold increase in mortality. It is likely that ATC exists whenever there is the combination of shock and tissue trauma (e.g. major surgery). ATC is the component of trauma-induced coagulopathy (TIC) which is ultimately multifactorial (Figure 2.1).

Ongoing bleeding with fluid and red blood cell resuscitation leads to a dilution of coagulation factors which worsens the coagulopathy. In addition, the acidosis induced by the hypoperfused state leads to decreased function of the coagulation proteases, resulting in coagulopathy and further haemorrhage. The reduced tissue perfusion includes reduced blood supply to muscle beds. Underperfused muscle is unable to generate heat and hypothermia ensues. Coagulation functions poorly at low temperatures and there is further haemorrhage, further hypoperfusion and worsening acidosis and hypothermia. These three factors result in a downward spiral leading to physiological exhaustion and death (Figure 2.1).

Medical therapy has a tendency to worsen this effect. Intravenous blood and fluids are cold and exacerbate hypothermia. Further heat is lost by opening body cavities during surgery. Surgery usually leads to further bleeding and many crystalloid fluids are themselves acidic (e.g. normal saline has a pH of 6.7). Every effort must therefore be made to rapidly identify and stop haemorrhage, and to avoid (preferably) or limit physiological exhaustion from coagulopathy, acidosis and hypothermia.

Definitions

Revealed and concealed haemorrhage

Haemorrhage may be revealed or concealed. Revealed haemorrhage is obvious external haemorrhage, such as exsanguination from an open arterial wound or from massive haematemesis from a duodenal ulcer.

Concealed haemorrhage is contained within the body cavity and must be suspected, actively investigated and controlled. In trauma, haemorrhage may be concealed within the chest, abdomen, pelvis, retroperitoneum or in the limbs with contained vascular injury or associated with long-bone fractures. Examples of non-traumatic concealed haemorrhage include occult gastrointestinal bleeding or ruptured aortic aneurysm.

Primary, reactionary and secondary haemorrhage

Primary haemorrhage is haemorrhage occurring immediately due to an injury (or surgery). Reactionary haemorrhage is delayed haemorrhage (within 24 hours) and is usually due to dislodgement of clot by resuscitation, normalisation of blood pressure and vasodilatation. Reactionary haemorrhage may also be due to technical failure, such as slippage of a ligature.

Secondary haemorrhage is due to sloughing of the wall of a vessel. It usually occurs 7–14 days after injury and is precipitated by factors such as infection, pressure necrosis (such as from a drain) or malignancy.

Surgical and non-surgical haemorrhage

Surgical haemorrhage is due to a direct injury and is amenable to surgical control (or other techniques such as angioembolisation). Non-surgical haemorrhage is the general ooze from all raw surfaces due to coagulopathy and cannot be stopped by surgical means (except packing). Treatment requires correction of the coagulation abnormalities.

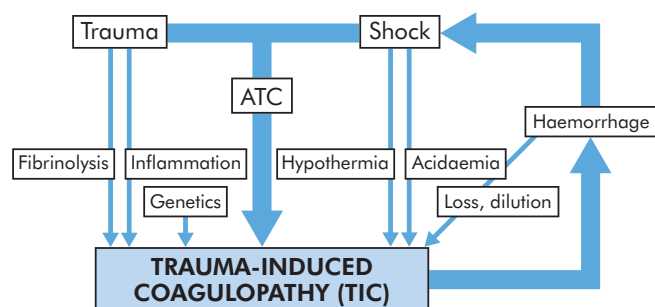

Figure 2.1 Trauma-induced coagulopathy.

Degree and classification

The adult human has approximately 5 litres of blood (70 mL/kg children and adults, 80 mL/kg neonates). Estimation of the amount of blood that has been lost is difficult, inaccurate and usually underestimates the actual value.

External haemorrhage is obvious, but it may be difficult to estimate the actual volume lost. In the operating room, blood collected in suction apparatus can be measured and swabs soaked in blood weighed.

The haemoglobin level is a poor indicator of the degree of haemorrhage as it represents a concentration and not an absolute amount. In the early stages of rapid haemorrhage, the haemoglobin concentration is unchanged (as whole blood is lost). Later, as fluid shifts from the intracellular and interstitial spaces into the vascular compartment, the haemoglobin and haematocrit levels will fall.

The amount of haemorrhage can be classified into classes 1–4 based on the estimated blood loss required to produce certain physiological compensatory changes (Table 2.4). Although conceptually useful, there is variation across ages (the young compensate well, the old very poorly), variation between individuals (athletes versus the obese) and variation due to confounding factors (e.g. concomitant medications, pain).

Treatment should therefore be based upon the degree of hypovolaemic shock according to vital signs, preload assessment, base deficit and, most importantly, the dynamic response to fluid therapy. Patients who are 'non-responders' or 'transient responders' are still bleeding and must have the site of haemorrhage identified and controlled.

Table 2.4 Traditional classification of haemorrhagic shock.

	Class			
	1	2	3	4
Blood volume lost as percentage of total	<15%	15–30%	30–40%	>40%

Management

Identify haemorrhage

External haemorrhage may be obvious, but the diagnosis of concealed haemorrhage may be more difficult. Any shock should be assumed to be hypovolaemic until proved otherwise, and similarly, hypovolaemia should be assumed to be due to haemorrhage until this has been excluded.

Immediate resuscitative manoeuvres

Direct pressure should be placed over the site of external haemorrhage. Airway and breathing should be assessed and controlled as necessary. Large-bore intravenous access should be instituted and blood drawn for cross-matching (see Cross-matching below). Emergency blood should be requested if the degree of shock and ongoing haemorrhage warrants this.

Identify the site of haemorrhage

Once haemorrhage has been considered, the site of haemorrhage must be rapidly identified. Note this is not to definitively

identify the exact location, but rather to define the next step in haemorrhage control (operation, angiocoilisation, endoscopic control).

Clues may be in the history (previous episodes, known aneurysm, non-steroidal therapy for gastrointestinal (GI) bleeding) or examination (nature of blood – fresh, melaena; abdominal tenderness, etc.). For shocked trauma patients, the external signs of injury may suggest internal haemorrhage, but haemorrhage into a body cavity (thorax, abdomen) must be excluded with rapid investigations (chest and pelvis x-ray, abdominal ultrasound or diagnostic peritoneal aspiration).

Investigations for blood loss must be appropriate to the patient's physiological condition. Rapid bedside tests are more appropriate for profound shock and exsanguinating haemorrhage than investigations such as computed tomography (CT) which take time. Patients who are not actively bleeding can have a more methodical, definitive work-up.

Haemorrhage control

The bleeding, shocked patient must be moved rapidly to a place of haemorrhage control. This will usually be in the operating room but may be the angiography or endoscopy suites. These patients require surgical and anaesthetic support and full monitoring and equipment must be available.

Haemorrhage control must be achieved rapidly so as to prevent the patient entering the triad of coagulopathy–acidosis–hypothermia and physiological exhaustion. There should be no unnecessary investigations or procedures prior to haemorrhage control to minimize the duration and severity of shock. This includes prolonged attempts to volume resuscitate the patient prior to surgery, which will result in further hypothermia and clotting factor dilution until the bleeding is stopped. Attention should be paid to correction of coagulopathy with blood component therapy to aid surgical haemorrhage control.

Surgical intervention may need to be limited to the minimum necessary to stop bleeding and control sepsis. More definitive repairs can be delayed until the patient is haemodynamically stable and physiologically capable of sustaining the procedure. This concept of tailoring the operation to match the patient's physiology and staged procedures to prevent physiological exhaustion is called 'damage control surgery' – a term borrowed from the military which ensures continued functioning of a damaged ship above conducting complete repairs which would prevent rapid return to battle (Summary box 2.4).

Once haemorrhage is controlled, patients should be aggressively resuscitated, warmed and coagulopathy corrected. Attention should be paid to fluid responsiveness and the end points of resuscitation to ensure that patients are fully resuscitated and to reduce the incidence and severity of organ failure.

Summary box 2.4

Damage control surgery

- Arrest haemorrhage
- Control sepsis
- Protect from further injury
- Nothing else

Damage control resuscitation

These concepts have been combined into a new paradigm for the management of trauma patients with active haemorrhage called damage control resuscitation (DCR). The four central strategies of DCR are:

- 1 Anticipate and treat acute traumatic coagulopathy
- 2 Permissive hypotension until haemorrhage control
- 3 Limit crystalloid and colloid infusion to avoid dilutional coagulopathy
- 4 Damage control surgery to control haemorrhage and preserve physiology.

Damage control resuscitation strategies have been shown to reduce mortality and morbidity in patients with exsanguinating trauma and may be applicable in other forms of acute haemorrhage.

TRANSFUSION

The transfusion of blood and blood products has become commonplace since the first successful transfusion in 1818. Although the incidence of severe transfusion reactions and infections is now very low, in recent years it has become apparent that there is an immunological price to be paid from the transfusion of heterologous blood, leading to increased morbidity and decreased survival in certain population groups (trauma, malignancy). Supplies are also limited, and therefore the use of blood and blood products must always be judicious and justifiable for clinical need (Table 2.5).

Blood and blood products

Blood is collected from donors who have been previously screened before donating, to exclude any donor whose blood may have the potential to harm the patient or to prevent possible harm that donating a unit of blood may have on the donor. In the UK, up to 450 mL of blood is drawn, a maximum of three times each year. Each unit is tested for evidence of hepatitis B, hepatitis C, HIV-1, HIV-2 and syphilis. Donations are leukodepleted as a precaution against variant Creutzfeldt–Jakob disease (this may also reduce the immunogenicity of the transfusion). The ABO and rhesus D blood group is determined, as well as the presence of irregular red cell antibodies. The blood is then processed into subcomponents.

Whole blood

Whole blood is now rarely available in civilian practice as it is an inefficient use of the limited resource. However, whole blood transfusion has significant advantages over packed cells as it is coagulation factor rich and, if fresh, more metabolically active than stored blood.

Packed red cells

Packed red blood cells are spun-down and concentrated packs of red blood cells. Each unit is approximately 330 mL and has a haematocrit of 50–70 per cent. Packed cells are stored in a SAG-M solution (saline–adenine–glucose–mannitol) to increase shelf life to 5 weeks at 2–6°C. (Older storage regimens included storage in CPD – citrate–phosphate–dextrose solutions which have a shelf life of 2–3 weeks.)

Table 2.5 History of blood transfusion.

1492	Pope Innocent VIII suffers a stroke and receives a blood transfusion from three ten-year-old boys (paid a ducat each). All three boys died, as did the pope later that year
1665	Richard Lower in Oxford conducts the first successful canine transfusions
1667	Jean-Baptiste Denis reports successful sheep–human transfusions
1678	Animal–human transfusions are banned in France because of the poor results
1818	James Blundell performs the first successful documented human transfusion in a woman suffering post-partum haemorrhage. She received blood from her husband and survived
1901	Karl Landsteiner discovers the ABO system
1914	The Belgian physician Albert Hustin performed the first non-direct transfusion, using sodium citrate as an anticoagulant
1926	The British Red Cross instituted the first blood transfusion service in the world
1939	The Rhesus system was identified and recognised as the major cause of transfusion reactions

Fresh-frozen plasma

Fresh-frozen plasma (FFP) is rich in coagulation factors and is removed from fresh blood and stored at –40 to –50°C with a two-year shelf life. It is the first-line therapy in the treatment of coagulopathic haemorrhage (see below under Management of coagulopathy). Rhesus D-positive FFP may be given to a rhesus D-negative woman although it is possible for seroconversion to occur with large volumes due to the presence of red cell fragments, and rhesus D immunization should be considered.

Cryoprecipitate

Cryoprecipitate is a supernatant precipitate of FFP and is rich in factor VIII and fibrinogen. It is stored at –30°C with a two-year shelf life. It is given in low fibrinogen states or factor VIII deficiency.

Platelets

Platelets are supplied as a pooled platelet concentrate and contain about $250 \times 10^9/L$. Platelets are stored on a special agitator at 20–24°C and have a shelf life of only 5 days. Platelet transfusions are given to patients with thrombocytopenia or with platelet dysfunction who are bleeding or undergoing surgery.

Patients are increasingly presenting on antiplatelet therapy such as aspirin or clopidogrel for reduction of cardiovascular risk. Aspirin therapy rarely poses a problem but control of haemorrhage on the more potent platelet inhibitors can be extremely difficult. Patients on clopidogrel who are actively bleeding and undergoing major surgery may require almost continuous infusion of platelets during the course of the procedure. Arginine vasopressin or its analogues (DDAVP) have also been used in this patient group, although with limited success.

Prothrombin complex concentrates

Prothrombin complex concentrates (PCC) are highly purified concentrates prepared from pooled plasma. They contain factors II, IX and X. Factor VII may be included or produced separately. It is indicated for the emergency reversal of anticoagulant (warfarin) therapy in uncontrolled haemorrhage.

Autologous blood

It is possible for patients undergoing elective surgery to pre-donate their own blood up to 3 weeks before surgery for retransfusion during the operation. Similarly, during surgery blood can be collected in a cell-saver which washes and collects red blood cells which can then be returned to the patient.

Indications for blood transfusion

Blood transfusions should be avoided if possible, and many previous uses of blood and blood products are now no longer considered appropriate use. The indications for blood transfusion are as follows:

- acute blood loss, to replace circulating volume and maintain oxygen delivery;
- perioperative anaemia, to ensure adequate oxygen delivery during the perioperative phase;
- symptomatic chronic anaemia, without haemorrhage or impending surgery.

Transfusion trigger

Historically, patients were transfused to achieve a haemoglobin >10 g/dL. This has now been shown to not only be unnecessary but also to be associated with an increased morbidity and mortality compared to lower target values. A haemoglobin level of 6 g/dL is acceptable in patients who are not actively bleeding, not about to undergo major surgery and are not symptomatic. There is some controversy as to the optimal haemoglobin level in some patient groups, such as those with cardiovascular disease, sepsis and traumatic brain injury. Although conceptually a higher haemoglobin improves oxygen delivery, there is little clinical evidence at this stage to support higher levels in these groups (Table 2.6).

Table 2.6 Perioperative red blood cell transfusion criteria.

Haemoglobin level (g/dL)	Indications
<6	Probably will benefit from transfusion
6–8	Transfusion unlikely to be of benefit in the absence of bleeding or impending surgery
>8	No indication for transfusion in the absence of other risk factors.

Blood groups and cross-matching

Human red cells have on their cell surface many different antigens. Two groups of antigens are of major importance in surgical practice – the ABO and rhesus systems.

ABO system

These are strongly antigenic and are associated with naturally occurring antibodies in the serum. The system consists of three allelic genes – A, B and O which control synthesis of enzymes that add carbohydrate residues to cell surface glycoproteins. A and B genes add specific residues while O gene is an amorph and does not transform the glycoprotein. The system allows for six possible genotypes although there are only four phenotypes. Naturally occurring antibodies are found in the serum of those lacking the corresponding antigen (Table 2.7).

Blood group O is the universal donor type as it contains no antigens to provoke a reaction. Conversely, group AB individuals are ‘universal recipients’ and can receive any ABO blood type as they have no circulating antibodies.

Rhesus system

The rhesus D (Rh(D)) antigen is strongly antigenic and is present in approximately 85 per cent of the population in the UK. Antibodies to the D antigen are not naturally present in the serum of the remaining 15 per cent of individuals, but their formation may be stimulated by the transfusion of Rh-positive red cells, or acquired during delivery of a Rh(D)-positive baby.

Acquired antibodies are capable, during pregnancy, of crossing the placenta and, if present in a Rh(D)-negative mother, may cause severe haemolytic anaemia and even death (hydrops fetalis) in a Rh(D)-positive fetus *in utero*. The other minor blood group antigens may be associated with naturally occurring antibodies, or may stimulate the formation of antibodies on relatively rare occasions.

Transfusion reactions

If antibodies present in the recipient's serum are incompatible with the donor's cells, a transfusion reaction will result. This usually takes the form of an acute haemolytic reaction. Severe immune-related transfusion reactions due to ABO incompatibility result in potentially fatal complement-mediated intravascular haemolysis and multiple organ failure. Transfusion reactions from other antigen systems are usually milder and self-limiting.

Febrile transfusion reactions are non-haemolytic and are usually caused by a graft-versus-host response from leukocytes in transfused components. Such reactions are associated with fever, chills or rigors. The blood transfusion should be stopped immediately. This form of transfusion reaction is rare with leukodepleted blood.

Cross-matching

To prevent transfusion reactions, all transfusions are preceded by ABO and rhesus typing of both donor and recipient blood to ensure compatibility. The recipient's serum is then mixed with the donor's cells to confirm ABO compatibility and to test for rhesus and any other blood group antigen–antibody reaction.

Full cross-matching of blood may take up to 45 minutes in most laboratories. In more urgent situations, ‘type specific’ blood is provided which is only ABO/rhesus matched and can be issued within 10–15 minutes. Where blood must be given emergently, group O (universal donor) blood is given (O– to females, O+ to males).

Karl Landsteiner, 1868–1943, Professor of Pathological Anatomy, University of Vienna, Austria. In 1909 he classified the human blood groups into A, B, AB and O. For this he was awarded the Nobel Prize for Physiology or Medicine in 1930.

Table 2.7 ABO blood group system.

Phenotype	Genotype	Antigens	Antibodies	Frequency (%)
O	OO	O	Anti-A, anti-B	46
A	AA or AO	A	Anti-B	42
B	BB or BO	B	Anti-A	9
AB	AB	AB	None	3

When blood transfusion is prescribed and blood is administered, it is essential that the correct patient receives the correct transfusion. Two healthcare personnel should check the patient details against the prescription and the label of the donor blood. In addition, the donor blood serial number should also be checked against the issue slip for that patient. Provided these principles are strictly adhered to, the number of severe and fatal ABO incompatibility reactions can be minimized.

Complications of blood transfusion

Complications from blood transfusion can be categorised as those arising from a single transfusion and those related to massive transfusion.

Complications from a single transfusion

Complications from a single transfusion include:

- incompatibility haemolytic transfusion reaction
- febrile transfusion reaction
- allergic reaction
- infection
 - bacterial infection (usually due to faulty storage)
 - hepatitis
 - HIV
 - malaria
- air embolism
- thrombophlebitis
- transfusion-related acute lung injury (usually from FFP).

Complications from massive transfusion

Complications from massive transfusion include:

- coagulopathy
- hypocalcaemia
- hyperkalaemia
- hypokalaemia
- hypothermia.

In addition, patients who receive repeated transfusions over long periods of time (e.g. patients with thalassaemia) may develop iron overload. (Each transfused unit of red blood cells contains approximately 250 mg of elemental iron.)

Management of coagulopathy

Correction of coagulopathy is not necessary if there is no active bleeding or haemorrhage is not anticipated (not due for surgery). However, coagulopathy following or during massive transfusion should be anticipated and managed aggressively. Standard guidelines are as follows:

- FFP if prothrombin time (PT) or partial thromboplastin time (PTT) >1.5 times normal
- cryoprecipitate if fibrinogen <0.8 g/L
- platelets if platelet count <50 × 10⁹/mL.

However, in the presence of non-surgical haemorrhage these tests take time to arrange and may underestimate the degree of coagulopathy. Treatment should then be instituted on the basis of clinical evidence of non-surgical bleeding.

There are pharmacological adjuncts to blood component therapy, although their indications and efficacy are yet to be established. Antifibrinolytics such as tranexamic acid and aprotinin are the most commonly administered. Recombinant factor VIIa is also under investigation for the treatment of non-surgical haemorrhage.

Blood substitutes

Blood substitutes are an attractive alternative to the costly process of donating, checking, storing and administering blood – and due to the immunogenic and potential infectious complications associated with transfusion.

There are several oxygen-carrying blood substitutes under investigation in animal or early clinical trials. Blood substitutes are either biomimetic or abiotic. Biomimetic substitutes mimic the standard oxygen-carrying capacity of the blood and are haemoglobin based. Abiotic substitutes are synthetic oxygen carriers and are currently primarily perfluorocarbon based.

Haemoglobin is seen as the obvious candidate for developing an effective blood substitute. Various engineered molecules are under clinical trials, based on human, bovine or recombinant technologies. Second-generation perfluorocarbon emulsions are also showing potential in clinical trials.

CHAPTER 3

Wounds, tissue repair and scars

LEARNING OBJECTIVES

To understand:

- Normal healing and how it can be adversely affected
- How to manage wounds of different types, of different structures and at different sites
- Aspects of disordered healing that lead to chronic wounds
- The variety of scars and their treatment

INTRODUCTION

Wound healing is a mechanism whereby the body attempts to restore the integrity of the injured part. This falls far short of tissue regeneration by pluripotent cells, seen in some amphibians, and is often detrimental, as seen in the problems created by scarring, such as adhesions, keloids, contractures and cirrhosis of the liver. Several factors may influence healing (Summary box 3.1). However, a clean incised wound in a healthy person where there is no skin loss will follow a set pattern as outlined below.

NORMAL WOUND HEALING

This is variously described as taking place in three or four phases, the most commonly agreed being:

- 1 the inflammatory phase;
- 2 the proliferative phase;
- 3 the remodelling phase (maturing phase).

Occasionally, a haemostatic phase is referred to as occurring before the inflammatory phase, or a destructive phase following inflammation consisting of the cellular cleansing of the wound by macrophages (Figure 3.1).

The inflammatory phase begins immediately after wounding and lasts 2–3 days. Bleeding is followed by vasoconstriction and thrombus formation to limit blood loss. Platelets stick to the damaged endothelial lining of vessels, releasing adenosine diphosphate (ADP), which causes thrombocytic aggregates to fill the wound. When bleeding stops, the platelets then release several cytokines from their alpha granules. These are platelet-derived growth factor (PDGF), platelet factor IV and transforming growth factor beta (TGFβ). These attract inflammatory cells such as polymorphonuclear lymphocytes (PMN) and macrophages. Platelets and the local injured tissue release vasoactive amines, such as histamine, serotonin and prostaglandins, which increase vascular permeability, thereby aiding infiltration of these inflammatory cells. Macrophages remove devitalised tissue and microorganisms while regulating fibroblast activity in the proliferative phase of healing. The initial framework for structural support of cells is provided by fibrin produced by fibrinogen. A more historical (Latin) description of this phase is described in four words: rubor (redness), tumour (swelling), calor (heat) and dolor (pain).

The proliferative phase lasts from the third day to the third week, consisting mainly of fibroblast activity with the production of collagen and ground substance (glycosaminoglycans and proteoglycans), the growth of new blood vessels as capillary loops (angiogenesis) and the re-epithelialisation of the

Summary box 3.1

Factors influencing healing of a wound

- Site of the wound
- Structures involved
- Mechanism of wounding
 - Incision
 - Crush
 - Crush avulsion
- Contamination (foreign bodies/bacteria)^a
- Loss of tissue
- Other local factors
 - Vascular insufficiency (arterial or venous)
 - Previous radiation
 - Pressure
- Systemic factors
 - Malnutrition or vitamin and mineral deficiencies
 - Disease (e.g. diabetes mellitus)
 - Medications (e.g. steroids)
 - Immune deficiencies (e.g. chemotherapy, acquired immunodeficiency syndrome (AIDS))
 - Smoking

^a In explosions, the contamination may consist of tissue such as bone from another individual.

Figure 3.1 The phases of healing. (a) Early inflammatory phase with platelet-enriched blood clot and dilated vessels. (b) Late inflammatory phase with increased vascularity and increase in polymorphonuclear lymphocytes and lymphocytes (round cells). (c) Proliferative phase with capillary buds and fibroblasts. (d) Mature contracted scar.

wound surface. Fibroblasts require vitamin C to produce collagen. The wound tissue formed in the early part of this phase is called granulation tissue. In the latter part of this phase, there is an increase in the tensile strength of the wound due to increased collagen, which is at first deposited in a random fashion and consists of type III collagen.

The remodelling phase is characterised by maturation of collagen (type I replacing type III until a ratio of 4:1 is achieved). There is a realignment of collagen fibres along the lines of tension, decreased wound vascularity and wound contraction due to fibroblast and myofibroblast activity.

NORMAL HEALING IN SPECIFIC TISSUES

Bone

The phases are as above, but periosteal and endosteal proliferation leads to callus formation, which is immature bone consisting of osteoid (mineralised by hydroxyapatite and laid down by osteoblasts). In the remodelling phase, cortical structure and the medullary cavity are restored. If fracture ends are accurately opposed and rigidly fixed, callus formation is minimal and primary healing occurs. If a gap exists, then secondary healing may lead to delayed union, non-union or malunion.

Nerve

Distal to the wound, Wallerian degeneration occurs. Proximally, the nerve suffers traumatic degeneration as far as the last node of Ranvier. The regenerating nerve fibres are attracted to their receptors by neurotrophism, which is mediated by growth factors,

hormones and other extracellular matrix trophins. Nerve regeneration is characterised by profuse growth of new nerve fibres which sprout from the cut proximal end. Overgrowth of these, coupled with poor approximation, may lead to neuroma formation.

Tendon

While following the normal pattern of wound healing, there are two main mechanisms whereby nutrients, cells and new vessels reach the severed tendon. These are **intrinsic**, which consists of vincular blood flow and synovial diffusion, and **extrinsic**, which depends on the formation of fibrous adhesions between the tendon and the tendon sheath. The random nature of the initial collagen produced means that the tendon lacks tensile strength for the first 3–6 weeks. Active mobilisation prevents adhesions limiting range of motion, but the tendon must be protected by splintage in order to avoid rupture of the repair.

ABNORMAL HEALING

Some of the adverse influences on wound healing are listed in Summary box 3.1. Delayed healing may result in loss of function or poor cosmetic outcome. The aim of treatment is to achieve healing by primary intention and so reduce the inflammatory and proliferative responses (Summary box 3.2).

Healing by primary intention is also known as healing by first intention. This occurs when there is apposition of the wound edges and minimal surrounding tissue trauma that causes least inflammation and leaves the best scar. Delayed primary intention healing occurs when the wound edges are not opposed immediately, which may be necessary in contaminated or untidy wounds. The inflammatory and proliferative phases of healing are well established when delayed closure of the wound is carried out. This is also called healing by tertiary intention in some texts and will result in a less satisfactory scar than would result after healing by primary intention. Secondary healing or healing by secondary intention occurs in wounds that are left open and allowed to heal by granulation, contraction and epithelialisation.

Summary box 3.2

Classification of wound closure and healing

- Primary intention
 - Wound edges opposed
 - Normal healing
 - Minimal scar
- Secondary intention
 - Wound left open
 - Heals by granulation, contraction and epithelialisation
 - Increased inflammation and proliferation
 - Poor scar
- Tertiary intention (also called delayed primary intention)
 - Wound initially left open
 - Edges later opposed when healing conditions favourable

Augustus Volney Waller, 1816–1870, a general practitioner of Kensington, London, UK (1842–1851), who subsequently worked as a physiologist in Bonn, Germany; Paris, France; Birmingham, UK; and Geneva, Switzerland.

TYPES OF WOUNDS – TIDY VERSUS UNTIDY

The site injured, the structures involved in the injury and the mechanism of injury (e.g. incision or explosion) all influence healing and recovery of function. This has led to the management of wounds based upon their classification into tidy and untidy (Table 3.1 and Figure 3.2). The surgeon’s aim is to convert untidy to tidy by removing all contaminated and devitalised tissue.

Primary repair of all structures (e.g. bone, tendon, vessel and nerve) may be possible in a tidy wound, but a contaminated wound with dead tissue requires debridement on one or several occasions before definitive repair can be carried out (the concept of ‘second look’ surgery). This is especially true in injuries caused by explosions, bullets or other missiles, where the external wound itself may appear much smaller than the wider extent of the injured tissues deep to the surface. Multiple debridements are often required after crushing injuries in road traffic accidents or in natural disasters such as earthquakes, where fallen masonry causes widespread muscle damage and compartment syndromes (see Compartment syndromes below). Any explosion where

there are multiple victims at the same site or where there has been a suicide-related explosion will carry the risk of tissue and viral contamination. Appropriate tests for hepatitis and HIV viruses are required.

Table 3.1 Tidy versus untidy wounds.

Tidy	Untidy
Incised	Crushed or avulsed
Clean	Contaminated
Healthy tissues	Devitalised tissues
Seldom tissue loss	Often tissue loss

MANAGING THE ACUTE WOUND

The surgeon must remember to examine the whole patient according to acute trauma life support (ATLS) principles. A stab wound in the back can be missed just as easily in the reality of the accident and emergency room as in a fictitious detective novel. The wound itself should be examined, taking into consideration the site and the possible structures damaged (Figure 3.3). It is essential to assess movement and sensation while watching for pain and listening to the patient. Tetanus cover should be noted and appropriate treatment carried out.

A bleeding wound should be elevated and a pressure pad applied. Clamps should not be put on vessels blindly as nerve damage is likely and vascular anastomosis is rendered impossible.

In order to facilitate examination, adequate analgesia and/or anaesthesia (local, regional or general) are required. General anaesthesia is often needed in children. In limb injuries, particularly those of the hand, a tourniquet should be used in order to facilitate visualisation of all structures. Due care should be taken with tourniquet application, avoiding uneven pressure and noting the duration of tourniquet time.

After assessment, a thorough debridement is essential. Abrasions, ‘road rash’ (following a fall from a motorbike) and explosions all cause dirt tattooing and require the use of a scrubbing brush or even excision under magnification. A wound should be explored and debrided to the limit of blood staining. Devitalised tissue must be excised until bleeding occurs with the obvious

Figure 3.2 (a) Tidy incised wound on the finger. (b) Untidy avulsed wound on the hand.

The term ‘debridement’ was introduced by the great French surgeon in Napoleon’s army, Dominique Jean Larrey (1766–1842). He used it to describe the removal of bullets, bits of cloth, loose bits of bone and soft tissue.

Figure 3.3 Facial trauma – apparent tissue loss but none found after careful matching.

exception of nerves, vessels and tendons. These may survive with adequate revascularisation subsequently or by being covered with viable tissue such as that brought in by skin or muscle flaps.

The use of copious saline irrigation or pulsed jet lavage (where the instrumentation is available) can be less destructive than knife or scissors when debriding. However, it has been suggested that pulsed jet lavage can implant dirt into a deeper plane and care should be taken to avoid this complication. Muscle viability is judged by the colour, bleeding pattern and contractility.

In a tidy wound, repair of all damaged structures may be attempted. Repair of nerves under magnification (loupes or microscope) using 8/0 or 10/0 monofilament nylon is usual. Vessels such as the radial or ulnar artery may be repaired using similar techniques. Tendon repairs, particularly those in the hand, benefit from early active mobilisation as this minimises adhesions between the tendon and the tendon sheath (see above under Tendon for extrinsic tendon healing mechanism).

Skin cover by flap or graft may be required as skin closure should always be without tension and should allow for the oedema typically associated with injury and the inflammatory phase of healing. A flap brings in a new blood supply and can be used to cover tendon, nerve, bone and other structures that would not provide a suitable vascular base for a skin graft. A skin graft has no inherent blood supply and is dependent on the recipient site for nutrition.

SOME SPECIFIC WOUNDS

Bites

Most bites involve either puncture wounds or avulsions. Small animal bites are common in children (Figure 3.4) and require cleansing and treatment according to the principles outlined in Summary box 3.3, usually under general anaesthetic.

Ear, tip of nose and lower lip injuries are most usually seen in victims of human bites. A boxing-type injury of the metacarpophalangeal joint may result from a perforating contact with the teeth of a victim. Anaerobic and aerobic organism prophylaxis is required as bite wounds typically have high virulent bacterial counts.

Puncture wounds

Wounds caused by sharp objects should be explored to the limit of tissue blood staining. Needle-stick injuries should be treated according to the well-published protocols because of hepatitis

Figure 3.4 Dog bite in a child.

Summary box 3.3

Managing the acute wound

- Cleansing
- Exploration and diagnosis
- Debridement
- Repair of structures
- Replacement of lost tissues where indicated
- Skin cover if required
- Skin closure without tension
- All of the above with careful tissue handling and meticulous technique

and human immunodeficiency virus (HIV) risks. X-ray examination should be carried out in order to rule out retained foreign bodies in the depth of the wound.

Haematoma

If large, painful or causing neural deficit, a haematoma may require release by incision or aspiration. In the gluteal or thigh region, there may be an associated disruption of fat in the form of a fat fracture, which results in an unsightly groove but intact skin. An untreated haematoma may also calcify and therefore require surgical exploration if symptomatic.

Degloving

Degloving occurs when the skin and subcutaneous fat are stripped by avulsion from its underlying fascia, leaving neurovascular structures, tendon or bone exposed. A degloving injury may be open or closed. An obvious example of an open degloving is a ring avulsion injury with loss of finger skin (Figure 3.5). A closed degloving may be a rollover injury, typically caused by a motor vehicle over a limb. Such an injury will extend far further than expected, and much of the limb skin may be non-viable (Figure 3.6). Examination under anaesthetic is required with a radical excision of all non-bleeding skin, as judged by bleeding dermis. Fluorescein can be administered intravenously while the patient is anaesthetised. Under ultraviolet light, viable (perfused) skin will show up as a fluorescent yellowish green colour, and the non-viable skin for excision is clearly mapped out. However, the main objection to this method is that of possible anaphylactic shock due to fluorescein sensitivity. Most surgeons therefore rely upon serial excision until punctate dermal bleeding is obvious.

Figure 3.5 Degloving hand injury.

Figure 3.6 Degloving buttock injury.

Figure 3.7 Meshed split-skin graft.

Split-skin grafts can be harvested from the degloved non-viable skin and meshed (Figure 3.7) to cover the raw areas resulting from debridement.

Compartment syndromes

Compartment syndromes typically occur in closed lower limb injuries. They are characterised by severe pain, pain on passive movement of the affected compartment muscles, distal sensory disturbance and, finally, by the absence of pulses distally (a late sign). They can occur in an open injury if the wound does not extend into the affected compartment.

Compartment pressures can be measured using a pressure monitor and a catheter placed in the muscle compartment. If pressures are constantly greater than 30 mmHg or if the above clinical signs are present, then fasciotomy should be performed. Fasciotomy involves incising the deep muscle fascia and is best carried out via longitudinal incisions of skin, fat and fascia (Figure 3.8). The muscle will be then seen bulging out through the fasciotomy opening. The lower limb can be decompressed via two incisions, each being lateral to the subcutaneous border of the tibia. This gives access to the two posterior compartments and to the peroneal and anterior compartments of the leg. In crush injuries that present several days after the event, a late fasciotomy can be dangerous as dead muscle produces

Figure 3.8 Fasciotomy of the lower leg.

myoglobin which, if suddenly released into the bloodstream, causes myoglobinuria with glomerular blockage and renal failure. In the late treatment of lower limb injuries, therefore, it may be safer to amputate the limb once viable and non-viable tissues have demarcated.

High-pressure injection injuries

The use of high-pressure devices in cleaning, degreasing and painting can cause extensive closed injuries through small entry wounds. The liquid injected spreads along fascial planes, a common site being from finger to forearm. The tissue damage is dependent upon the toxicity of the substance and the injection pressure. Treatment is surgical with wide exposure, removal of the toxic substance and thorough debridement. Preoperative x-rays may be helpful where air or lead-based paints can be seen. It should be noted that amputation rates following high-pressure injection injuries are reported as being over 45 per cent. Delayed or conservative treatment is therefore inappropriate.

CHRONIC WOUNDS

Leg ulcers

In developed countries, the most common chronic wounds are leg ulcers. An ulcer can be defined as a break in the epithelial continuity. A prolonged inflammatory phase leads to overgrowth of granulation tissue, and attempts to heal by scarring leave a fibrotic margin. Necrotic tissue, often at the ulcer centre, is called slough. The more common aetiologies are listed in Summary box 3.4.

Summary box 3.4

Aetiology of leg ulcers

- Venous disease leading to local venous hypertension (e.g. varicose veins)
- Arterial disease, either large vessel (atherosclerosis) or small vessel (diabetes)
- Arteritis associated with autoimmune disease (rheumatoid arthritis, lupus, etc.)
- Trauma – could be self-inflicted
- Chronic infection – tuberculosis/syphilis
- Neoplastic – squamous or basal cell carcinoma, sarcoma

Figure 3.9 Pressure ulcer.

A chronic ulcer, unresponsive to dressings and simple treatments, should be biopsied to rule out neoplastic change, a squamous cell carcinoma known as a Marjolin's ulcer being the most common. Effective treatment of any leg ulcer depends on treating the underlying cause, and diagnosis is therefore vital. Arterial and venous circulation should be assessed, as should sensation throughout the lower limb. Surgical treatment is only indicated if non-operative treatment has failed or if the patient suffers from intractable pain. Meshed skin grafts (Figure 3.7) are more successful than sheet grafts and have the advantage of allowing mobilisation, as any tissue exudate can escape through the mesh. It should be stressed that the recurrence rate is high in venous ulceration, and patient compliance with a regime of hygiene, elevation and elastic compression is essential.

Pressure sores

These can be defined as tissue necrosis with ulceration due to prolonged pressure. Less preferable terms are bed sores, pressure ulcers and decubitus ulcers. They should be regarded as preventable but occur in approximately 5 per cent of all hospitalised patients (range 3–12 per cent in published literature). There is a higher incidence in paraplegic patients, in the elderly and in the severely ill patient. The most common sites are listed in Summary box 3.5.

Summary box 3.5

Pressure sore frequency in descending order

- Ischium
- Greater trochanter
- Sacrum
- Heel
- Malleolus (lateral then medial)
- Occiput

A staging system for description of pressure sores devised by the American National Pressure Ulcer Advisory Panel is shown in Table 3.2.

If external pressure exceeds the capillary occlusive pressure (over 30 mmHg), blood flow to the skin ceases leading to tissue anoxia, necrosis and ulceration (Figure 3.9). Prevention is obviously the best treatment with good skin care, special pressure dis-

Table 3.2 Staging of pressure sores.

Stage	Description
1	Non-blanchable erythema without a breach in the epidermis
2	Partial-thickness skin loss involving the epidermis and dermis
3	Full-thickness skin loss extending into the subcutaneous tissue but not through underlying fascia
4	Full-thickness skin loss through fascia with extensive tissue destruction, maybe involving muscle, bone, tendon or joint

person cushions or foams, the use of low air loss and air-fluidised beds and urinary or faecal diversion in selected cases. Pressure sore awareness is vital, and the bed-bound patient should be turned at least every 2 hours, with the wheelchair-bound patient being taught to lift themselves off their seat for 10 seconds every 10 minutes.

Surgical management of pressure sores follows the same principles involved in acute wound treatment (Summary box 3.4). The patient must be well motivated, clinically stable with good nutrition and adhere to the preventative measures advised postoperatively. Preoperative management of the pressure sore involves adequate debridement, and the use of vacuum-assisted closure (VAC) may help to provide a suitable wound for surgical closure (see below). The aim is to fill the dead space and to provide durable sensate skin. Large skin flaps that include muscle are best and, occasionally, an intact sensory innervated area can be included (e.g. extensor fascia lata flap with lateral cutaneous nerve of the thigh). If possible, use a flap that can be advanced further if there is recurrence and that does not interfere with the planning of neighbouring flaps that may be used in the future.

Vacuum-assisted closure

This is now more correctly known as negative pressure wound closure. Applying intermittent negative pressure of approximately -125 mmHg appears to hasten debridement and the formation of granulation tissue in chronic wounds and ulcers. A foam dressing is cut to size to fit the wound. A perforated wound drain is placed over the foam, and the wound is sealed with a transparent adhesive film. A vacuum is then applied to the drain (Figure 3.10). Negative pressure may act by decreasing oedema, by removing interstitial fluid and by increasing blood flow. As a result, bacterial counts decrease and cell proliferation increases, thereby creating a suitable bed for graft or flap cover.

NECROTISING SOFT-TISSUE INFECTIONS

These are rare but often fatal. They are most commonly polymicrobial infections with Gram-positive aerobes (*Staphylococcus aureus*, *S. pyogenes*), Gram-negative anaerobes (*Escherichia coli*,

Hans Christian Joachim Gram, 1853–1938, Professor of Pharmacology (1891–1900) and of Medicine (1900–1923), Copenhagen, Denmark, described this method of staining bacteria in 1884.

Figure 3.10 Vacuum-assisted closure dressing of a large wound.

Pseudomonas, *Clostridium*, *Bacteroides*) and β -haemolytic *Streptococcus*. There is usually a history of trauma or surgery with wound contamination. Sometimes, the patient's own defence mechanism may be deficient. These infections are characterised by sudden presentation and rapid progression. The fact that deeper tissues are involved often leads to a late or missed diagnosis (Figure 3.11). Clinical signs are shown in Summary box 3.6.

Summary box 3.6

Signs and symptoms of necrotising infections

- Unusual pain
- Oedema beyond area of erythema
- Crepitus
- Skin blistering
- Fever (often absent)
- Greyish drainage ('dishwater pus')
- Pink/orange skin staining
- Focal skin gangrene (late sign)
- Shock, coagulopathy and multiorgan failure

There are two main types of necrotising infections: clostridial (gas gangrene) and non-clostridial (streptococcal gangrene and necrotising fasciitis). The variant of necrotising fasciitis with toxic shock syndrome results from *Streptococcus pyogenes* and is often called the 'flesh-eating bug' in this situation. Treatment is surgical excision with tissue biopsies being sent for culture and diagnosis. Wide raw areas requiring skin grafting often result.

SCARS

The maturation phase of wound healing has been discussed above and represents the formation of what is described as a scar. The immature scar becomes mature over a period lasting a year or more, but it is at first pink, hard, raised and often itchy. The disorganised collagen fibres become aligned along stress lines with their strength being in their weave rather than in their amount (this has been compared with steel wool being slowly woven into a cable). As the collagen matures and becomes denser, the scar becomes almost acellular as the fibroblasts and blood vessels reduce. The external appearance of the scar

becomes paler, while the scar becomes softer, flattens and its itchiness diminishes. Most of these changes occur over the first three months but a scar will continue to mature for one to two years. Tensile strength will continue to increase but would not be expected to exceed 60–80 per cent that of normal skin.

Scars are often described as being atrophic, hypertrophic and keloid. An atrophic scar is pale, flat and stretched in appearance, often appearing on the back and areas of tension. It is easily traumatised as the epidermis and dermis are thinned. Excision and resuturing may only rarely improve such a scar.

A hypertrophic scar is defined as excessive scar tissue that does not extend beyond the boundary of the original incision or wound. It results from a prolonged inflammatory phase of wound healing and from unfavourable scar siting (i.e. across the lines of skin tension). In the face, these are known as the lines of facial expression.

A keloid scar is defined as excessive scar tissue that extends beyond the boundaries of the original incision or wound (Figure 3.12). Its aetiology is unknown, but it is associated with elevated levels of growth factor, deeply pigmented skin, an inherited tendency and certain areas of the body (e.g. a triangle whose points are the xiphisternum and each shoulder tip).

The histology of both hypertrophic and keloid scars shows excess collagen with hypervascularity, but this is more marked in keloids where there is more type III collagen.

The treatment of both hypertrophic and keloid scars is difficult and is summarised in Summary box 3.7.

Hypertrophic scars improve spontaneously with time, whereas keloid scars do not.

Summary box 3.7

Treatment of hypertrophic and keloid scars

- Pressure – local moulds or elasticated garments
- Silicone gel sheeting (mechanism unknown)
- Intralesional steroid injection (triamcinolone)
- Excision and steroid injections^a
- Excision and postoperative radiation (external beam or brachytherapy)^a
- Intralesional excision (keloids only)
- Laser – to reduce redness (which may resolve in any event)
- Vitamin E or palm oil massage (unproven)

^aAll excisions have high rates of recurrence.

Figure 3.11 Necrotising fasciitis of the anterior abdominal wall.

Figure 3.12 Multiple keloid scars.

Figure 3.13 Dirt-ingrained scar.

AVOIDABLE SCARRING

If an acute wound has been managed correctly (Summary box 3.4), most of the problems described above should not occur. However, the surgeon should always stress to the patient that there will be a scar of some description after wounding, be it planned or accidental. A dirt-ingrained (tattooed) scar is usually preventable by proper initial scrubbing and cleansing of the wound (Figure 3.13). Late treatment may require excision of the scar or pigment destruction by laser.

Mismatched or misaligned scars result from a failure to recognise normal landmarks, such as the lip vermilion/white roll interface, eyelid and nostril free margins and hair lines such as those relating to eyebrows and moustache. Treatment consists of excision and resuturing.

Poorly contoured scars can be stepped, grooved or pincushioned. Most are caused by poor alignment of deep structures such as muscle or fat, but trapdoor or pincushioned scars are often unavoidable unless the almost circumferential wound can be excised initially. Late treatment consists of scar excision and correct alignment of deeper structures or, as in the case of a trapdoor scar, an excision of the scar margins and repair using W- or Z-plasty techniques.

Suture marks may be minimised by using monofilament sutures that are removed early (3–5 days). Sutures inserted under tension will leave marks. Wounds can be strengthened post-suture removal by the use of sticky strips. Fine sutures (6/0 or smaller) placed close to the wound margins tend to leave less scarring. Subcuticular suturing avoids suture marks either side of the wound or incision.

CONTRACTURES

Where scars cross joints or flexion creases, a tight web may form restricting the range of movement at the joint. This may be referred to as a contracture and can cause hyperextension or hyperflexion deformity (Figure 3.14). In the neck, it may interfere with head extension (Figure 3.15). Treatment may be simple involving multiple Z-plasties (Figure 3.16) or more complex requiring the inset of grafts or flaps. Splintage and intensive physiotherapy are often required postoperatively.

Figure 3.14 Burn contractures showing hyperextended fingers and hyperflexed elbow.

Figure 3.15 Post-traumatic (chainsaw) midline neck contracture.

Figure 3.16 Multiple Z-plasty release of finger contracture.

Basic surgical skills and anastomoses

LEARNING OBJECTIVES

To understand:

- The principles of skin and abdominal incisions
- The principles of wound closure

To know the principles in performing:

- Bowel anastomoses
- Vascular anastomoses

To be aware of:

- The principles of drain usage
- The principles of diathermy, ligasure and harmonic scalpel

INCISIONS

Skin incisions

Skin incisions should be made with a scalpel with the blade being pressed firmly down at right angles to the skin and then drawn gently across the skin in the desired direction to create a clean incision, the site and extent of which should have been clearly planned by the surgeon. It is important not to incise the skin obliquely as such a shearing mechanism can lead to necrosis of the undercut edge. The incision is facilitated by tension being applied across the line of the incision by the fingers of the non-dominant hand, but the surgeon must ensure that at no time is the scalpel blade directed at their own fingers as any slip may result in a self-inflicted injury. Blades for skin incisions usually have a curved cutting margin, while those used for an arteriotomy or drain site insertion have a sharp tip (Figure 4.1). Scalpels should at all times be passed in a kidney dish rather than by a direct hand-to-hand process as this can lead to a needle stick-like injury. Diathermy, laser and harmonic scalpels can be used instead of blades when opening deeper tissues, as it is felt that they can reduce blood loss and save operating time, and may reduce postoperative pain.

When planning a skin incision, four factors should be considered:

- 1 **Skin tension lines** (Langer's lines). These lines represent the orientation of the dermal collagen fibres and any incision placed parallel to these lines result in a better scar (Figure 4.2).
- 2 **Anatomical structure.** Incisions should avoid bony prominences and crossing skin creases if possible, and take into consideration underlying structures, such as nerves and vessels.
- 3 **Cosmetic factors.** Any incision should be made bearing in mind the ultimate cosmetic result, especially in exposed parts of the body, as an incision is the only part of the operation the patient sees.
- 4 **Adequate access for the procedure.** The incision must be functionally effective for the procedure in hand as any com-

Figure 4.1 Scalpel blade sizes and shapes. The 22-blade is often used for abdominal incisions, the 11-blade for arteriotomy and the 15-blade for minor surgical procedures.

promise purely on cosmetic grounds may render the operation ineffective or even dangerous.

Occasionally, it may be necessary to excise a skin lesion with a circular incision in an area when the direction of Langer's lines are not apparent. However, once the circular incision has been made, it can often be observed that the circular incision is converted to an ellipse thus indicating the lines of tension. This circular incision should then be formally converted into an elliptical incision, remembering the rule of thumb that 'an elliptical incision must be at least three times as long as it is wide'

Figure 4.2 Langer's lines. These depict the orientation of the dermal collagen fibres. Reproduced with permission from Thomas WEG, Senninger N (eds). *Short stay surgery*. Berlin: Springer-Verlag, 2008.

for the wound to heal without tension. Occasionally, 'dog ears' remain in the corner of elliptical incisions in spite of adequate care having been taken during formation and primary closure of an elliptical wound. In these situations, it is advisable to pick up the 'dog ear' with a skin hook and excise it as shown in Figure 4.3. This allows for a satisfactory cosmetic outcome.

Abdominal incisions

As for skin incisions, all abdominal incisions should be planned in advance of surgery and take into consideration access to the relevant organs, surface landmarks, pain control and cosmetic

Figure 4.3 Dealing with a 'dog ear' at the corner of an elliptical incision. Reproduced with permission from Thomas WEG, Senninger N (eds). *Short stay surgery*. Berlin: Springer-Verlag, 2008.

outcome, e.g. transverse incisions tend to be associated with fewer respiratory complications and a better cosmetic outcome. In the past, traditionally vertical midline or paramedian incisions were used for the majority of abdominal procedures, but there is a current trend to utilise transverse incisions wherever possible as this minimises postoperative complications. The incision should be carried deeper through the subcutaneous tissues and then, depending on the site of the incision (Figure 4.4), the muscle layers should be divided or split, and the peritoneum displayed. This should be picked up between two clips and gently incised to ensure there is no damage to the underlying organs. This is particularly important in the emergency situation when there may be dilatation of the bowel. Every incision should be made with closure in mind, and the layers appropriately delineated. Mass closure of the abdominal wall is usually advocated using large bites and short steps in the closure technique using either non-absorbable (e.g. nylon or polypropylene) or very slowly absorbable suture material (e.g. polydioxanone suture (PDS)). It has been estimated that for abdominal wall closure, the length of the suture material should be at least four times the length of the wound to be closed to minimise the risk of abdominal dehiscence or later incisional hernia. Similar attention to detail applies to laparoscopic surgery, where access is of equal importance as correct port site placement and closure is crucial to the success of the operative procedure.

London: Churchill Livingstone (Elsevier Limited), 2004. 1, Midline; 2, Kocher's; 3, thoracoabdominal; 4, rectus split; 5, paramedian; 6, transverse; 7, McBurney's gridiron; 8, inguinal; 9, pfannenstiel; 10, McEvedy; 11, Rutherford Morison.

WOUND CLOSURE

The suturing of any incision or wound needs to take into consideration the site and tissues involved and the technique for closure should be chosen accordingly. There is no ideal wound closure technique that would be appropriate for all situations, and the ideal suture has yet to be produced, although many of the desired characteristics are listed in Summary box 4.1. Therefore, the correct choice of suture technique and suture material is vital, but will never compensate for inadequate

Summary box 4.1**Suture material: desired characteristics**

- Easy to handle
- Predictable behaviour in tissues
- Predictable tensile strength
- Sterile
- Glides through tissues easily
- Secure knotting ability
- Inexpensive
- Minimal tissue reaction
- Non-capillary
- Non-allergenic
- Non-carcinogenic
- Non-electrolytic
- Non-shrinkage

operative technique, and for any wound to heal well, there must be a good blood supply and no tension on the closure.

Clean uninfected wounds with a good blood supply heal by primary intention and so closure simply requires accurate apposition of the wound edges. However, if a wound is left open, it heals by secondary intention through the formation of granulation tissue, which is tissue composed of capillaries, fibroblasts and inflammatory cells. Wound contraction and epithelialisation assist in ultimate healing, but the process may take several weeks or months. Delayed primary closure or tertiary intention is utilised when there is a high probability of the wound being infected. The wound is left open for a few days and then if any infective process is resolved then the wound is closed to heal by primary intention. Skin grafting is another form of tertiary intention healing (Summary box 4.2).

Summary box 4.2**Types of wound healing**

- Primary intention
 - Clean wound
- Secondary intention
 - Healthy granulation tissue
 - Over-exuberant granulation tissue
 - Infected sloughy wound
 - Black eschar
- Tertiary intention
 - Delayed closure
 - Skin grafting

When choosing suture materials, there are certain specific requirements depending on the tissues to be sutured, e.g. vascular anastomoses require smooth, non-absorbable, non-elastic material, while biliary anastomoses require an absorbable material that will not promote tissue reaction or stone formation. When using absorbable material, the time in which wound support is required and maintained will vary according to the tissues in which it is inserted. Furthermore, certain tissues require wound support for longer than others, for example muscular aponeuroses compared with subcutaneous tissues. It is therefore crucial for the surgeon to select the suture material and suture technique

that will most effectively achieve the desired objective for each wound closure or anastomosis.

Suture materials**History**

Sutures are best made of soft thread, not too hard twisted that it may sit easier on the tissue, nor are too few nor too many of either of them to be put in.

Aurelius Cornelius Celsus, 25BC–AD50

Multiple examples of early surgery abound, with East African tribes ligating blood vessels with tendons strips, and closing wounds with acacia thorns pushed through the wound with strips of vegetable matter wound round these in a figure of eight. A South American method of wound closure involved using large black ants to bite the wound together with their pincers or jaws acting like skin clips, and then the ant's body was twisted off leaving the head in place keeping the wound apposed. By 1000BC, Indian surgeons were using horsehair, cotton and leather sutures while in Roman times, linen and silk and metal clips, called fibulae, were commonly used to close gladiatorial wounds. By the end of the nineteenth century, developments in the textile industry led to major advances, and both silk and catgut became popular as suture materials. Lister believed that catgut soaked in chromic acid (a form of tanning) prevented early dissolution in body fluids and tissues, while Moynihan felt that chromic catgut was ideal as it could be sterilised, was non-irritant to tissues, kept its strength until its work was done and then disappeared. However, catgut is no longer in use as it causes an inflammatory cellular reaction with release of proteases and may also carry the risk of prion transmission if of bovine origin.

Suture characteristics

There are five characteristics of any suture material that need to be considered:

- 1 **Physical structure.** Suture material may be monofilament or multifilament. Monofilament suture material is smooth and tends to slide through tissues easily without any sawing action, but is more difficult to knot effectively. Such material can be easily damaged by gripping it with needle holder or forceps and this can lead to fracture of the suture material. Multifilament or braided sutures are much easier to knot, but have a surface area of several thousand times that of monofilament sutures and thus have a capillary action and interstices where bacteria may lodge and be responsible for persistent infection or sinuses. In order to overcome some of these problems, certain materials are produced as a braided suture which is coated with silicone in order to make it smooth.
- 2 **Strength.** The strength of a suture material depends upon its constituent material, its thickness and how it is handled in the tissues. Suture material thickness is classified according to its diameter in tenths of a millimetre (Table 4.1), although

Berkley George Andrew Moynihan, (Lord Moynihan of Leeds), 1865–1936, Professor of Clinical Surgery, University of Leeds, Leeds, UK. Moynihan felt that English surgeons knew little about the work of their colleagues both at home and abroad. Therefore, in 1909, he established a small travelling club which in 1929 became the Moynihan Chirurgical Club. It still exists today. He took a leading part in founding the British Journal of Surgery in 1913 and became the first chairman of the editorial committee until his death.

Aurelius Cornelius Celsus, Roman physician, 25BC–AD50.

Joseph Lister (Lord Lister), Professor of Surgery in Glasgow, Edinburgh and King's College Hospital, London and Vice President of Royal College of Surgeons of England, 1827–1912.

Alexis Carrel, 1873–1944, a surgeon from Lyons in France who worked at the Rockefeller Institute for Medical Research in New York, NY, USA. He received the Nobel Prize for Physiology or Medicine in 1912 'in recognition for his works on vascular suture and the transplantation of blood vessels and organs'.

Gladiators were so called because they fought with a Roman sword called a 'gladius'.

Table 4.1 Size of suture material.

Metric (EurPh)	Range of diameter (mm)	USP ('old')
1	0.100–0.149	5–0
1.5	0.150–0.199	4–0
2	0.200–0.249	3–0
3	0.300–0.349	2–0
3.5	0.350–0.399	0
4	0.400–0.499	1
5	0.500–0.599	2

the figure assigned is also dependent upon the nature of the material, e.g. absorbable material and non-absorbable material, such as polypropylene, may differ in their designations. The tensile strength of a suture can be expressed as the force required to break it when pulling the two ends apart, but is only a useful approximation as to its strength in the tissues, as what matters is the material's *in vivo* strength. Absorbable sutures show a decay of this strength with the passage of time and although a material may last in the tissues for the stated period in the manufacturer's product profile, its tensile strength cannot be relied on *in vivo* for this entire period. Materials such as catgut (no longer in use in the UK) has a tensile strength of only about a week while PDS will remain strong in the tissues for several weeks. However, even non-absorbable sutures do not necessarily maintain their strength indefinitely, and may degrade with time. Those non-absorbable materials of synthetic origin, such as polypropylene, probably retain their tensile strength indefinitely and do not change in mass in the tissues, although it is still possible for them to fracture. Non-absorbable materials of biological origin, such as silk, will definitely fragment with time and lose their strength, and such materials should never be used in vascular anastomoses for fear of late fistula formation.

3 Tensile behaviour. Suture materials behave differently depending upon their deformability and flexibility. Some may be 'elastic' in which the material will return to its original length once any tension is released, while others may be 'plastic' in which case this phenomenon does not occur. Sutures may be deformable in that a circular cross-section may be converted to an oval shape, or they may be more rigid and have the somewhat irritating capacity to kink and coil. Many synthetic materials demonstrate 'memory' in which they keep curling up in the shape that they adopted within the packaging. A sharp but gentle pull on the suture material helps to diminish this memory, but the more memory a suture material has, the less is the knot security. Therefore, knotting technique also plays a significant role in any suture line's tensile strength and it is important to recognise that sutures lose 50 per cent of their strength at the knot.

4 Absorbability. Suture materials may be absorbable (Table 4.2) or non-absorbable (Table 4.3) and this property must be taken into consideration when choosing suture materials for specific wound closures or anastomoses. Sutures for use in the biliary or urinary tract need to be absorbable in order to minimise the risk of stone production. However, a vascular anastomosis requires a non-absorbable material and it is wise to avoid braided material as platelet adherence may predispose to distal embolisation. Non-absorbable materials tend to

be preferred where persistent strength is required and, as an artificial graft or prosthesis never heals fully or integrates into a host artery, persistent monofilament suture materials, such as polypropylene, are almost universally used.

5 Biological behaviour. The biological behaviour of suture material within the tissues depends upon the constituent raw material. Biological or natural sutures, such as catgut, are proteolysed, but this involves a process that is not entirely predictable and can cause local irritation and such materials are therefore seldom used. Man-made synthetic polymers are hydrolysed and their disappearance in the tissues is more predictable. However, the presence of pus, urine or faeces influences the final result and renders the outcome more unpredictable. There is also some evidence that in the gut, cancer cells may accumulate at sites where sutures persist, possibly giving rise to local recurrence. For this reason, synthetic materials that have a greater predictability and elicit minimal tissue reaction may have an important non-carcinogenic property.

Table 4.2 Non-absorbable suture materials.

Suture	Types	Raw material	Tensile strength	Absorption rate	Tissue reaction	Contraindications	Frequent uses	How supplied
Silk	Braided or twisted multifilament.	Natural protein	Loses 20% when wet; 80–100% lost by 6 months.	Fibrous encapsulation in body at 2–3 weeks	Moderate to high	Not for use with vascular prostheses or in tissues requiring prolonged approximation under stress	Ligation and suturing when long-term tissue support is necessary	10/0–2 with needles, 4/0–1 without needles
	Dyed or undyed. Coated (with wax or silicone) or uncoated	Raw silk from silkworm	Because of tissue reactions and unpredictability, silk is increasingly not recommended	Absorbed slowly over 1–2 years	Not recommended	Risk of infection and tissue reaction makes silk unsuitable for routine skin closure	For securing drains externally	
Linen	Twisted	Long staple flax fibres	Stronger when wet Loses 50% at 6 months; 30% remains at 2 years	Non-absorbable Remains encapsulated in body tissues	Moderate	Not advised for use with vascular prostheses	Ligation and suturing in gastrointestinal surgery. No longer in common use in most centres	3/0–1 with needles, 3/0–1 without needles
Surgical steel	Monofilament or multifilament	An alloy of iron, nickel and chromium	Infinite (>1 year)	Non-absorbable Remains encapsulated in body tissues	Minimal	Should not be used in conjunction with prosthesis of different metal	Closure of sternotomy wounds Previously found favour for tendon and hernia repairs	Monofilament: 5/0–5 with needles; multifilament: 5/0–3/0 with needles
Nylon	Monofilament or braided multifilament Dyed or undyed	Polyamide polymer	Loses 15–20% per year	Degrades at approximately 15–20% per year	Low	None	General surgical use, e.g. skin closure, abdominal wall mass closure, hernia repair, plastic surgery, neurosurgery, microsurgery, ophthalmic surgery	Monofilament: 11/0–2 with needles (including loops in some sizes), 4/0–2 without needles; multifilament: 6/0–2 with needles, 3/0–1 without needles
Polyester	Monofilament or braided multifilament Dyed or undyed Coated (polybutylate or silicone) or uncoated	Polyester (polyethylene terephthalate)	Infinite (>1 year)	Non-absorbable: remains encapsulated in body tissues	Low	None	Cardiovascular, ophthalmic, plastic and general surgery	Monofilament: (ophthalmic) 11/10; 10/0 with needles; multifilament: 5/0–1 with needles
Polybutester	Monofilament. Dyed or undyed	Polybutylene terephthalate and polytetramethylene ether glycol	Infinite (>1 year)	Non-absorbable: remains encapsulated in body tissues	Low	None	Exhibits a degree of elasticity. Particularly favoured for use in plastic surgery	7/0–1 with needles
Polypropylene	Monofilament. Dyed or undyed	Polymer of propylene	Infinite (>1 year)	Non-absorbable: remains encapsulated in body tissues	Low	None	Cardiovascular surgery, plastic surgery, ophthalmic surgery, general surgical subcuticular skin closure	10/0–1 with needles

Table 4.3 Absorbable suture materials.

Suture	Types	Raw material	Tensile strength retention <i>in vivo</i>	Absorption rate	Tissue reaction	Contraindications	Frequent uses	How supplied
Catgut	Plain	Collagen derived from healthy sheep or cattle	Lost within 7–10 days Marked patient variability Unpredictable and not recommended	Phagocytosis and enzymatic degradation within 7–10 days	High	Not for use in tissues which heal slowly and require prolonged support Synthetic absorbables are superior	Ligate superficial vessels, suture subcutaneous tissues Stomas and other tissues that heal rapidly	6/0–1 with needles; 4/0–3 without needles
Catgut	Chromic	Collagen derived from healthy sheep or cattle Tanned with chromium salts to improve handling and to resist degradation in tissue	Lost within 21–28 days Marked patient variability Unpredictable and not recommended	Phagocytosis and enzymatic degradation within 90 days	Moderate	As for plain catgut Synthetic absorbables superior	As for plain catgut	6/0–3 with needles; 5/0–3 without needles
Polyglactin	Braided multifilament	Copolymer of lactide and glycolide in a ratio of 90:10, coated with polyglactin and calcium stearate	Approximately 60% remains at 2 weeks Approximately 30% remains at 3 weeks	Hydrolysis minimal until 5–6 weeks. Complete absorption 60–90 days	Mild	Not advised for use in tissues which require prolonged approximation under stress	General surgical use where absorbable sutures required, e.g. gut anastomoses, vascular ligatures. Has become the 'workhorse' suture for many applications in most general surgical practices, including undyed for subcuticular wound closures. Ophthalmic surgery	8/0–2 with needles; 5/0–2 without needles
Polyglyconate	Monofilament Dyed or undyed	Copolymer of glycolic acid and trimethylene carbonate	Approximately 70% remains at 2 weeks Approximately 55% remains at 3 weeks	Hydrolysis minimal until 8–9 weeks. Complete absorption by 180 days	Mild	Not advised for use in tissues which require prolonged approximation under stress	Popular in some centres as an alternative to Vicryl and PDS	7/0–2 with needles
Polyglycolic acid	Braided multifilament Dyed or undyed Coated or uncoated	Polymer of polyglycolic acid. Available with coating of inert, absorbable surfactant poloxamer 188 to enhance surface smoothness 87% excreted in urine within 3 days	Approximately 40% remains at 1 week Approximately 20% remains at 3 weeks	Hydrolysis minimal at 2 weeks, significant at 4 weeks. Complete absorption 60–90 days	Minimal	Not advised for use in tissues which require prolonged approximation under stress	Uses as for other absorbable sutures, in particular where slightly longer wound support is required	9/0–2 with needles; 9/0–2 without needles
Polydioxanone (PDS)	Monofilament Dyed or undyed	Polyester polymer	Approximately 70% remains at 2 weeks Approximately 50% remains at 4 weeks Approximately 14% remains at 8 weeks	Hydrolysis minimal at 90 days Complete absorption at 180 days	Mild	Not for use in association with heart valves or synthetic grafts, or in situations in which prolonged tissue approximation under stress is required	Uses as for other absorbable sutures, in particular where slightly longer wound support is required	Polydioxanone suture (PDS) 10/0–2 with needles
Polyglycaprone	Monofilament	Copolymer of glycolite and caprolactone	21 days maximum	90–120 days	Mild	No use for extended support	Subcuticular in skin, ligation, gastrointestinal and muscle surgery	8/0–2 with needles

Suture techniques

There are four frequently used suture techniques.

- 1 Interrupted sutures.** Interrupted sutures require the needle to be inserted at right angles to the incision and then to pass through both aspects of the suture line and exit again at right angles (Figure 4.5). It is important for the needle to be rotated through the tissues rather than to be dragged through for fear of unnecessarily enlarging the needle hole. As a guide, the distance from the entry point of the needle to the edge of the wound should be approximately the same as the depth of the tissue being sutured, and each successive suture should be placed at twice this distance apart (Figure 4.6). Each suture should reach into the depths of the wound and be placed at right angles to the axis of the wound. In linear wounds, it is sometimes easier to insert the middle suture first and then to complete the closure by successively inserting sutures, halving the remaining deficits in the wound length.
- 2 Continuous sutures.** For a continuous suture, the first suture is inserted in an identical manner to an interrupted suture, but the rest of the sutures are inserted in a continuous manner until the far end of the wound is reached (Figure 4.7). Each throw of the continuous suture should be inserted at right

Figure 4.7 Continuous suture technique. Reproduced with permission from Royal College of Surgeons of England. *The intercollegiate basic surgical skills course participants handbook*, edns 1–4. London: RCS.

Figure 4.8 Mattress suture techniques. Reproduced with permission from Royal College of Surgeons of England. *The intercollegiate basic surgical skills course participants handbook*, edns 1–4. London: RCS.

angles to the wound and this will mean that the externally observed suture material will usually lie diagonal to the axis of the wound. It is important to have an assistant who will follow the suture, keeping it at the same tension in order to avoid either purse stringing the wound by too much tension, or leaving the suture material too slack. There is more danger of producing too much tension by using too little suture length than there is of leaving the suture line too lax. Postoperative oedema will often take up any slack in the suture material. At the far end of the wound, this suture line should be secured either by using an Aberdeen knot or by tying the free end to the loop of the last suture to be inserted.

- 3 Mattress sutures.** Mattress sutures may be either vertical or horizontal and tend to be used to produce either eversion or inversion of a wound edge (Figure 4.8). The initial suture is inserted as for an interrupted suture, but then the needle either moves horizontally or vertically and traverses both edges of the wound once again. Such sutures are very useful in producing accurate approximation of wound edges, especially when the edges to be anastomosed are irregular in depth or disposition.
- 4 Subcuticular suture.** This technique is used in skin where a cosmetic appearance is important and where the skin edges may be approximated easily (Figure 4.9). The suture material used may be either absorbable or non-absorbable. For non-absorbable sutures, the ends may be secured by means of a collar and bead, or tied loosely over the wound. When absorbable sutures are used, the ends may be secured using a buried knot. Small bites of the subcuticular tissues are

Figure 4.9 Subcuticular suture technique. Reproduced with permission from Royal College of Surgeons of England. *The intercollegiate basic surgical skills course participants handbook*, edns 1–4. London: RCS.

taken on alternate sites of the wound and then gently pulled together thus approximating the wound edges without the risk of the cross-hatched markings of interrupted sutures.

Needles

In the past, needles had eyes in them and suture material had

to be loaded into them, which was not only time consuming, but it meant that the needle holes in tissues were considerably larger than the suture material being used. Currently, needles are eyeless or 'atraumatic' with the suture material embedded within the shank of the needle. The needle has three main parts (Figure 4.10):

Figure 4.11 Types of needle.

- 1 Shank
- 2 Body
- 3 Point.

The needle should be grasped by the needle holder approximately one-third of the way back from the rear of the needle avoiding both the shank and the point.

The body of the needle is either round, triangular or flattened. Round-bodied needles gradually taper to a point, while triangular needles have cutting edges along all three sides. The actual point of the needle can be round with a tapered end, conventional cutting which has the cutting edge facing the inside of the needle's curvature, or reversed cutting in which the cutting edge is on the outside (Figure 4.11). Round-bodied needles are designed to separate tissue fibres rather than cut through them and are commonly used in intestinal and cardiovascular surgery. Cutting needles are used where tough or dense tissue needs to be sutured, such as skin and fascia. Blunt-ended needles are now being advocated in certain situations, such as closure of the abdominal wall, in order to diminish the risk of needle-stick injuries in this era of virally transmitted disorders.

The choice of needle shape tends to be dictated by the accessibility of the tissue to be sutured, and the more confined the operative space, the more curved the needle. Hand-held straight needles may be used on skin, although today it is advocated that needle holders should be used in all cases to reduce the risk of needle-stick injuries. Half circle needles are commonly utilised in the gastrointestinal tract, while J-shaped needles, quarter circle needles and compound curvature needles are used in special situations such as the vagina, eye and oral cavity, respectively. The size of the needle tends to correspond with the gauge of the suture material, although it is possible to get similar sutures with differing needle sizes.

Knotting techniques

Knot tying is one of the most fundamental techniques in surgery and yet is often poorly performed. The principles behind a secure knot are poorly understood by many surgeons and sadly a poorly constructed knot may thus jeopardise an otherwise successful surgical procedure. The general principles behind knot tying include:

- The knot must be tied firmly, but without strangulating the tissues.
- The knot must be unable to slip or unravel.
- The knot must be as small as possible to minimise the amount of foreign material.
- The knot must be tightened without exerting any tension or pressure on the tissues being ligated, i.e. the knot should be bedded down carefully, only exerting pressure against counter-pressure from the index finger or thumb.
- During tying, the suture material must not be 'sawed' as this weakens the thread.
- The suture material must be laid square during tying, otherwise tension during tightening may cause breakage or fracture of the thread.
- When tying an instrument knot, the thread should only be grasped at the free end, as gripping the thread with artery forceps or needle holders can damage the material and again result in breakage or fracture.
- The standard surgical knot is the reef knot (Figure 4.12),

Figure 4.12 Standard knotting formation.

with a third throw for security, although with monofilament sutures such as for vascular surgery, six to eight throws are required for security.

- A granny knot involves two throws of the same type of throw and is a slip knot. It may be useful in achieving the right tension in certain circumstances, but must be followed by a standard reef knot to ensure security.
- When added security is required, a surgeon's knot using a two-throw technique is advisable to prevent slippage.
- When using a continuous suture technique, an Aberdeen knot may be used for the final knot. The free end of the suture is partially pulled through the final loop several times before being pulled through a final time completely prior to cutting.
- When the suture is cut after knotting, the ends should be left about 1–2 mm long to prevent unraveling. This is particularly important when using monofilament material.

Alternatives to sutures

Many alternatives to standard suture techniques now exist and are in common usage.

Skin adhesive strips

For the skin, self-adhesive tapes or steristrips may be used where there is no tension and not too much moisture, such as after a wide excision of a breast lump. They may also be used to minimise 'spreading' of a scar. Other adhesive polyurethane films, such as Opsite, Tegaderm or Bioclusive, may provide a similar benefit, while such transparent dressings also allow wound inspection and may protect against cross-infection.

Tissue glue

Tissue glue is also available based upon a solution of n-butyl-2-cyanoacrylate monomer. When it is applied to a wound, it polymerises to form a firm adhesive bond, but the wound does need to be clean, dry, with near perfect haemostasis and under no tension. Some specific uses have been described such as closing a laceration on the forehead of a fractious child in Accident and Emergency thus dispensing with local anaesthetic and sutures. Although it is relatively expensive, it is quick to use, does not delay wound healing and is associated with an allegedly low infection rate. Other tissue glues involve fibrin and work on the principles of converting fibrinogen to fibrin by thrombin with crosslinking by Factor XIII, and the addition of aprotinin to slow the break up of the fibrin network by plasmin. This process has good adhesive properties and has been used for haemostasis in the liver and spleen, for dural tears, in ear, nose and throat (ENT) and ophthalmic surgery, to attach skin grafts and also to prevent haemorrhagic collections under flaps. Fibrin glues have also been used to control gastrointestinal haemorrhage endoscopically, but do not work when the bleeding is brisk.

Staples

Mechanical stapling devices were first used successfully by Hümer Hütl in Hungary in 1908 to close the stomach after resection. Today, there is a wide range of mechanical devices with linear, side-to-side and end-to-end stapling devices that can be used both in the open surgery setting and laparoscopically. Most of these devices are disposable and relatively expensive, but their cost is offset by the saving of operative time and the potential increase in the range of surgery possible (see below).

Clips

Skin clips produce a very neat scar with good wound eversion and a minimal cross-hatching effect. They can be placed faster than suture insertion and have a lower predisposition to infection as they do not penetrate entirely through the wound and do not produce a complete track from one wound edge to the other. However, they can be uncomfortable for the patient and they require a special instrument to remove them. Furthermore, they tend to be a more expensive method for wound closure than simple suture techniques.

Stapling devices

In the gastrointestinal tract, stapling devices tend to apply two rows of staples, offset in relation to each other to produce a sound anastomosis (Figure 4.13). Many of them also simultaneously divide the bowel or tissue that has been stapled while other devices merely insert the staples and the bowel has to be divided separately. For all stapling devices, it is crucial for the surgeon to understand the principles behind each device and to know intimately the mechanism and function of the instrument.

- **End-to-end anastomoses.** Circular stapling devices allow tubes to be joined together and such instruments are in common use in the oesophagus and low rectum. The detached stapling head/anvil is introduced into one end of the bowel, usually being secured within it by means of a purse-string suture. The body of the device is then inserted into the other end of the bowel, either via the rectum for a low

rectal anastomosis, or via an enterotomy for an oesophago-jejunojejunostomy, and either the shaft is extended through a small opening in the bowel wall or is secured by a further purse-string suture. The head/anvil is reattached to the shaft and the two ends approximated. Once the device is fully closed as indicated by the green indicator in the window, the device is fired, and after unwinding, the stapler is gently withdrawn. It is important to assess the integrity of the anastomosis by examining the 'doughnuts' of tissue excised for completeness. It is essential that no extraneous tissue is allowed to become interposed between the two bowel walls on closing the stapler.

- **Transverse anastomoses.** These instruments, which come in different sizes, simply provide two rows of staples for a single transverse anastomosis. They are useful for closing bowel ends, and the larger sizes have been used to create gastric tubes and gastric partitioning. One technical point of importance is that the bowel should be divided before the instrument is reopened after firing, as the instrument is designed with a ridge along which to pass a scalpel to ensure the correct length cuff of bowel remains adjacent to the staple line. Down in the pelvis it may be helpful to use such a device with a moveable head (roticulator).
- **Intraluminal anastomoses.** These instruments have two limbs which can be detached. Each limb is introduced into a loop of bowel, the limbs reassembled and the device closed. On firing, two rows of staples are inserted either side of the divided bowel, the division occurring by means of a built-in blade that is activated at the same time as the insertion of staples. Such an instrument may be used in fashioning a gastro-jejunojejunostomy or jejuno-jejunojejunostomy and is used in ileal pouch formation.
- **Other devices.** Other devices are produced that will staple/ligate and divide blood vessels. Skin closure may also be undertaken using hand-held stapling devices rather than individually picking up staples/clips and inserting them as described above. Many of the intestinal stapling devices are now adapted to be inserted down cannulae during laparoscopic surgery, and although they look very different, the principles of function are identical to the open surgery variety.

THE PRINCIPLES OF ANASTOMOSES

Bowel anastomoses

The word anastomosis comes from the Greek 'ἀνα', without, and 'στόμα', a mouth, reflecting the join of a tubular viscus (bowel) or vessel (usually arteries) after a resection or bypass procedure. Prior to the nineteenth century, intestinal surgery was limited to exteriorisation by means of a stoma or closure of simple lacerations. Lembert then described his seromuscular suture technique for bowel anastomosis in 1826, while Senn advocated a two-layer technique for closure. Kocher's method utilised a two-layer anastomosis, first a continuous all-layer suture using catgut, then an inverting continuous (or interrupted) seromuscular layer suture using silk, which became the mainstay of bowel anastomoses for many years (Figure 4.14). However, Halsted favoured a one-layer extramucosal closure, and this was subsequently advocated by Matheson as it was felt to cause the least tissue necrosis or luminal narrowing (Figure 4.15). This technique has now become

Hümer Hütl, surgeon, St Stephen's Hospital, Budapest, Hungary, described his gastric stapler in 1908.

Figure 4.13 Standard stapling devices.

widely accepted, although it is essential that this is not confused with a seromuscular suture technique. The extramucosal suture must include the submucosa as this has a high collagen content and is the most stable suture layer in all sections of the gastrointestinal tract. There are several prospective randomised trials

between two-layer and single-layer anastomoses demonstrating that there is probably little to choose between these techniques, provided basic essentials as highlighted in Summary box 4.3 are observed. However, catgut and silk have been replaced by synthetic, usually absorbable, polymers.

Figure 4.14 Standard two-layer bowel anastomosis. Reproduced with permission from Kocher T, Harder F, Thomas WEG (eds). *Anastomosis techniques in the gastrointestinal tract*, 1st edn. Wollerau: Covidien, 2007.

In the past, great emphasis was placed on good bowel preparation prior to any anastomosis. The rationale was that with good bowel preparation and an empty bowel, there was less likelihood of faecal contamination and therefore it was probably not necessary to apply bowel clamps (even of the soft occlusion type). However, this tradition is now being challenged, and there is evidence to suggest that conventional bowel preparation provides little benefit, and indeed at times may prove detrimental to the outcome. In spite of this, many surgeons still use some form of bowel preparation, especially for colorectal surgery. Furthermore, if there is any risk of intestinal spillage during anastomosis, when bowel is unprepared or obstructed for example, atraumatic intestinal clamps should be used across the lumen of the bowel. Clamps should not impinge on the mesentery or the vasculature of the bowel for fear of damage to the vessels resulting in ischaemic changes. Ideally, the bowel edges should be pink and bleeding prior to anastomosis. Excessive bleeding from the bowel wall may need oversewing if natural haemostasis is inadequate.

For all intestinal anastomoses, the bowel ends must be brought together without tension. Stay sutures, which avoid the need for tissue forceps, are invaluable for displaying the bowel ends and help with the accurate alignment of the bowel and the placement of the sutures. If the anastomosis is being undertaken on mobile bowel, the anterior wall layer of sutures can be inserted, either in a continuous or interrupted manner, and then

the bowel rotated and the posterior wall sutured in an identical manner to the anterior wall. As the mesenteric edge of the bowel is the most difficult, especially when a fatty mesentery is present, this angle should be dealt with first, with the final sutures being inserted at the antimesenteric border which is far more accessible and visible. The apposition of bowel edges should be as accurate as possible and the suture bites should be approximately 3–5 mm deep and 3–5 mm apart depending on the thickness of the bowel wall. The suture materials should be of 2/0–3/0 size and made of an absorbable polymer, which can be braided (e.g. polyglactin), or monofilament (e.g. polydioxanone), mounted on an atraumatic round-bodied needle. Braided, coated sutures are the easiest to handle and knot.

It is crucial to make sure that only bowel of similar diameter is brought together to form an end-to-end anastomosis. In cases of major size discrepancy, a side-to-side or end-to-side anastomosis may be safer. In cases where the size discrepancy is not marked, a Cheatle split (making a cut into the antimesenteric border) may help to enlarge the lumen of distal, collapsed bowel and allow an end-to-end anastomosis to be fashioned. After all anastomoses, the mesentery should always be closed to avoid the later risk of an internal hernia through a persistent mesenteric defect. Care must be taken during closure of this defect to prevent damage to any mesenteric vessels running in the edge of the mesentery (Summary box 4.3).

In certain situations, stapling devices are used to fashion the anastomosis, but as they are expensive, most surgeons reserve them for specific indications, such as oesophageal, rectal and gastric pouch procedures. Several studies have shown them not to be cost effective in routine small bowel surgery, although many surgeons still use them for ease of use and to save time.

Summary box 4.3

Intestinal anastomoses

- Ensure good blood supply to both bowel ends before and after formation of anastomosis.
- Ensure the anastomosis is under no tension.
- Avoid risk to mesenteric vessels by clamps or sutures.
- Use atraumatic bowel clamps to minimise contamination.
- Interrupted and continuous single-layer suture techniques are adequate and safe.
- Stapling devices are an alternative when speed is required or access is a major factor.

Vascular anastomoses

Vascular anastomoses require an extremely accurate closure as they must be immediately watertight at the end of the operation when the vascular clamps are removed. In many cases, some form of prosthetic material or graft may be used which will never be integrated into the body tissues and so the integrity of the suture line needs to be permanent. For this reason, polypropylene is one of the best sutures as it is not biodegradable. It is used in its monofilament form, mounted on an atraumatic, curved, round-bodied needle. Knot security is important, and as polypropylene is monofilament and the anastomosis often depends on one final knot, several throws (between six and eight) of a well-laid reef knot are required. The suture line must be regular and watertight with a smooth intimal surface to minimise the risk of thrombosis and embolus, as well as to avoid any leakage. Suture size depends

on vessel calibre: 2/0 is suitable for the aorta, 4/0 for the femoral artery and 6/0 for the popliteal to distal arteries. Microvascular anastomoses are made using a loupe and an interrupted suture down to 10/0 size.

All vessel walls must be treated with great care avoiding causing any damage to the intima. If any significant manipulation is necessary, atraumatic forceps (such as DeBakey's) are utilised. Vascular clamps should be applied with great care, particularly for calcified vessels, and in some cases encircling rubber loops or intraluminal balloon catheters may be less traumatic for control. Vessels should always be sewn with the needle moving from within to without on the downstream edge of the vessel to avoid creating an intimal flap and to fix any atherosclerotic plaque. The tip of the needle should be inserted at right angles to the surface of the intima and the curve of the needle followed to prevent vessel trauma. The assistant should 'follow' by keeping the suture taut, and once the closure is complete, the distal clamp is released first, before the final watertight knot is made. This allows back-flow to clear any clot or air from the anastomosis. The proximal clamp can then be released, a process which minimises the risk of distal embolus. Suture bites should be placed an equal distance apart, with the bite size dependent on the vessel diameter. Care needs to be taken to avoid damaging the suture, which should not be gripped by any surgical instrument. All haemostats that are used to hold any suture material should be shod with soft rubber to prevent suture material damage.

A transverse arteriotomy is less likely to stenose following closure than a longitudinal arteriotomy, but may not give adequate access, and a longitudinal arteriotomy is easier to make. Therefore, a vein patch can be used if there is any danger of stenosis or doubt about the size of the lumen (Figure 4.16). The suture line can be started at the apex of the arteriotomy with a double-ended suture, and then carried down each side with the final knot being placed at the midpoint of the vein patch graft, and not at the far end. The suture should go from outside to inside on the graft and from inside to outside on the artery, again to minimise the risk of intimal flap formation.

When prosthetic material or grafts are used, similar non-absorbable monofilament sutures are used with the same in-out technique to ensure eversion of the graft edge and a smooth intimal surface. Again the needle should go from outside to inside on the graft and from inside to outside on the artery. Double-ended sutures make the procedures easier (Summary box 4.4).

DRAINS

Drains are inserted to allow fluid or air that might collect at an operation site or in a wound to drain freely to the surface. The fluid to be drained may include blood, serum, pus, urine, faeces,

Figure 4.16 Arteriotomy being closed by vein patch. Technique involves a double armed suture ensuring that the final knot is half way along one side of the arteriotomy. Summary box 4.4

Vascular anastomosis

- Non-absorbable monofilament suture material should be used, e.g. polypropylene.
- A smooth intimal suture line is essential.
- Knots require multiple throws in order to ensure security.
- The suture must pass from within outwards on the downflow aspect of the anastomosis.

bile or lymph. Drains may also allow wound irrigation in certain specific circumstances. The adequate drainage of fluid collections prevents the development of cavities or spaces that may delay wound healing. Their use can be regarded as prophylactic in elective surgery and therapeutic in emergency surgery. Three basic principles apply in the use of drains:

- 1 Open drains that utilise the principle of gravity
- 2 Semi-open drains that work on the principle of the capillary effect
- 3 Closed drains systems that utilise suction.

They may be placed through the wound or through a separate incision, although it has been clearly shown that placing them through the wound leads to an increased risk of wound infection. With regard to the indications for drainage, in the past drains were in common use ever since Lawson Tait in 1887 suggested 'when in doubt drain!' However, this edict has come under strong criticism recently and the value and use of drains has been the subject of close scrutiny, and their use still remains controversial.

Protagonists suggest that the use of drains may:

- remove any intraperitoneal or wound collection of ascites, serum, bile, chyle, pancreatic or intestinal secretion;
- act as a signal for any postoperative haemorrhage or anastomotic leakage;
- provide a track for later drainage.

However, the antagonists claim that the presence of a drain may:

- increase intra-abdominal and wound infections;
- increase anastomotic insufficiency;
- increase abdominal pain;
- increase hospital stay;
- decrease pulmonary function.

In reality, the use of drains currently tends to depend on a surgeon's individual preference. There are randomised controlled trials suggesting that their use in gastric, duodenal, small bowel, appendix and biliary surgery is unnecessary, and may cause more problems than benefits, and this is now reflected in current practice. There are also randomised controlled trials to suggest that they are also not required in colorectal, liver and pancreatic surgery and yet in today's practice the majority of surgeons will still utilise drains in these forms of surgery. The only area of alimentary tract surgery where drains are still routinely advocated is for oesophageal surgery, although even here the evidence is low with the level of evidence being only 5 and the level of recommendation being 'D' (i.e. based on expert opinion).

Specialist use of drains

There are certain clinical situations where specialist forms of drainage are required.

Chest drains

These are indicated for a pneumothorax, pleural effusion, haemothorax or to prevent the collection of fluid or air after thoracotomy. Once the drain has been inserted, it should be connected to an underwater sealed drain (Figure 4.17). This system allows air to leave the pleural cavity, but cannot draw it back in with the negative pressure that is created in the intrathoracic cavity. During the respiratory process, it should be checked that the meniscus of the fluid is swinging to ensure that the tube is not blocked. Suction can be applied to the venting tube at the bottle whenever there is significant drainage of fluid or air expected. Between 10 and 20 mm of mercury is adequate to obtain a gentle flow of bubbles from the chest cavity.

T-tube drains

After exploration of the common bile duct, a T-tube (Figure 4.18) may be inserted into the duct which allows bile to drain while the sphincter of Oddi is in spasm postoperatively. Once the sphincter relaxes, bile drains normally down the bile duct and into the duodenum. To assist cholestasis, it is often advisable to convert the lumen of the limb of the T into a gutter, which also facilitates removal.

Guided drainage

For many intra-abdominal collections or abscesses, drains may be inserted under ultrasound or computed tomography (CT)

control. In order for such drains to remain in site, the end is often fashioned with a pigtail to discourage inadvertent removal.

Removal of drains

A drain should be removed as soon as it is no longer required, as if left in, it can itself predispose to fluid collections as a result of tissue reaction. Indeed there is evidence that by 7 days only 20 per cent of drains are still functioning. It should be stressed how important it is to define the objective of each individual drain and to ensure that once that objective has been met, the drain is removed. If a drain is used at all, the following principles may apply:

- Drains put in to cover perioperative bleeding may usually be removed after 24 hours, e.g. thyroidectomy.
- Drains put in to drain serous collections usually can be removed after 5 days, e.g. mastectomy.
- Drains put in because of infection should be left until the infection is subsiding or the drainage is minimal.
- Drains put in to cover colorectal anastomoses should be removed at about 5–7 days. However, it should be stressed that in no way does a drain prevent any intestinal leakage, but merely may assist any such leakage to drain externally rather than to produce life-threatening peritonitis.
- Common bile duct T-tubes should remain in for 10 days. However, once the T-tube cholangiogram has shown that there is free flow of bile into the duodenum and that there are no retained stones, some surgeons like to clamp the T-tube prior to removal. The 10-day period is required to minimise the risk of biliary peritonitis after removal.
- Any suction drain should have the suction taken off prior to removal of the drain.
- During removal of a chest drain, the patient should be asked to breathe in and hold his breath, thus doing a Valsalva manoeuvre. In this way, no air is sucked into the pleural

cavity as the tube is removed. Once the drain is out, a previously inserted purse-string suture should be tied.

THE PRINCIPLES OF DIATHERMY: ELECTROSURGERY

For many years, short wave diathermy has proved a most valuable and versatile aid to surgical technique. Its most common use is in securing haemostasis by means of coagulation, but by varying the strength or wave form of the current produced, it can also result in a cutting effect. Both these effects have been used in open surgery, as well as in laparoscopic surgery or down intraluminal endoscopes as in transurethral resection of the prostate. However, although diathermy is a valuable surgical tool, many accidents have occurred due to surgeons being unaware of, or not fully understanding, the principles of its use. Most accidents are avoidable if the diathermy or electrocautery is used with care. It is therefore vital for a surgeon to have a sound understanding of the principles and practice of diathermy, and how to avoid complications.

The principle of diathermy

When an electrical current passes through a conductor, some of its energy appears as heat. The heat produced depends on:

- the intensity of the current;
- the wave form of the current;
- the electrical property of the tissues through which the current passes;
- the relative sizes of the two electrodes.

There are two basic types of diathermy system in use, monopolar diathermy and bipolar diathermy (Figure 4.19). In monopolar diathermy, which is the most commonly used form, an alternating current is produced by a suitable generator and passed to the patient via an active electrode which has a very small surface area. The current then passes through the tissues and returns via a very large surface plate (the indifferent electrode) back to the earth pole of the generator. As the surface area of contact of the active electrode is small in comparison to the indifferent electrode, the concentrated powerful current produces heat at the operative site. However, the large surface area electrode of the patient plate spreads the returning current over a wide surface area, so it is less concentrated and produces little heat.

In bipolar diathermy, the two active electrodes are usually represented by the limbs of a pair of diathermy forceps. Both forceps ends are therefore active and current flows between them and only the tissue held between the limbs of the forceps heats up. This form of diathermy is used when it is essential that the surrounding tissue should be free from either the risk of being burned or having current passed through them.

The effects of diathermy

Diathermy can be used for three purposes:

- 1 Coagulation: the sealing of blood vessels.
- 2 Fulguration: the destructive coagulation of tissues with charring.
- 3 Cutting: used to divide tissues during bloodless surgery.

In **coagulation**, a heating effect leads to cell death by dehydration and protein denaturation. Bleeding is therefore stopped by a combination of the distortion of the walls of the blood vessel,

Figure 4.19 The principles of diathermy. (a) Monopolar diathermy. (b) Bipolar diathermy. Reproduced with permission from Royal College of Surgeons of England. *The intercollegiate basic surgical skills course participants handbook*, edns 1–4. London: RCS.

coagulation of the plasma proteins, dried and shrunken dead tissue and stimulation of the clotting mechanism. In an ideal situation, intracellular temperatures should not reach boiling during coagulation, because if it does an unwanted cutting effect may be experienced.

Cutting occurs when sufficient heat is applied to the tissue to cause cell water to explode into steam. The cut current is a continuous wave form and the monopolar diathermy is most effective when the active electrode is held a very short distance from the tissues. This allows an electrical discharge to arc across the gap creating a series of sparks which produce the high temperatures needed for cutting.

In **fulguration**, the diathermy matching is set to coagulation and a higher effective voltage is used to make larger sparks jump an air gap thus fulgurating the tissues. This can continue until carbonisation or charring occurs. The voltage and power output can be varied by adjusting the duration of bursts of current, as well as its intensity to give a combination of both cutting and coagulation. This is known as blended current and provides both forms of diathermy activity.

Complications of diathermy

Electrocution

Today, diathermy machines are manufactured to very high safety standards which minimise the risk of any part of the machine becoming live with mains current. However, as with any such instrument, there must be regular and expert servicing.

Explosion

Sparks from the diathermy can ignite any volatile or inflammable gas or fluid within the theatre. Alcohol-based skin preparations can catch fire if they are allowed to pool on or around the patient. Furthermore, diathermy should not be used in the presence of explosive gases, including those which may occur naturally in the colon, especially after certain forms of bowel preparation, such as mannitol, which has now been banned for this use for this very reason.

Burns

These are the most common type of diathermy accidents in both open and endoscopic surgery. They occur when the current flows in some way other than that in which the surgeon intended and are far more common in monopolar than bipolar diathermy. These may occur as a result of:

- Faulty application of the indifferent electrode with inadequate contact area.
- The patient being earthed by touching any metal object, e.g. the Mayo table, the bar of an anaesthetic screen, an exposed metal arm rest or a leg touching the metal stirrups used in maintaining the lithotomy position.
- Faulty insulation of the diathermy leads, either due to cracked insulation or instruments such as towel clips pinching the cable.
- Inadvertent activity such as the accidental activation of the foot pedal, or accidental contact of the active electrode with other metal instruments, such as retractors, instruments or towel clips.

Channelling

Heat is produced wherever the current intensity is greatest. Normally, this would be at the tip of the active electrode, but if current passes up a narrow channel or pedicle to the active electrode, enough heat may be generated within this channel or pedicle to coagulate the tissues. This can prove disastrous, for example,

- coagulation of the penis in a child undergoing circumcision;
- coagulation of the spermatic cord when the electrode is applied to the testis.

In such situations, diathermy should not be used, or if it is necessary, then bipolar diathermy should be employed.

Pacemakers

Diathermy currents can interfere with the working of a pacemaker with its obvious potential danger to the patient's health. Modern pacemakers are designed to be inhibited by high frequency interference, so that the patient may receive no pacing stimulation at all while the diathermy is in use. Certain demand pacemakers may revert to the fixed rate of pacing and therefore it would be important for the anaesthetist to have a magnet

available so that these can be reset if necessary. In most cases, it is therefore wise to undertake precautions and to use bipolar diathermy wherever possible. If monopolar diathermy is required, then the patient plate should be sited as far away from the pacemaker as possible so that the path of the current does not pass through the heart or the vicinity of the pacemaker. Monitoring of the heart rate should be undertaken throughout the operation and a defibrillator should always be available in case a dysrhythmia develops at any time.

Laparoscopic surgery

Diathermy burns are a particular hazard of laparoscopic surgery due to the nature of the visibility of the instrumentation and the actual structure of the instruments used. Such burns may occur by:

- Diathermy of the wrong structure because of lack of clarity of vision or misidentification.
- Faulty insulation of any of the laparoscopic instruments or equipment.
- Intraperitoneal contact of the diathermy with another metal instrument while activating the pedal.
- Inadvertent activation of the pedal while the diathermy tip is out of vision of the camera.
- Retained heat in the diathermy tip touching susceptible structures, such as bowel.
- Capacitance coupling (Figure 4.20). This is a phenomenon in which a capacitor is created by having an insulator sandwiched between two metal electrodes. This can be created in situations where there is a metal laparoscopic port and the diathermy hook is passed through it. The insulation of the diathermy hook acts as the sandwiched insulator and by means of electromagnetic induction, the diathermy current flowing through the hook can induce a current in the metal port, which can potentially damage intraperitoneal structures. In most cases, this current is dissipated from the metal port through the abdominal wall, but if a plastic cuff is used, this dissipation of current does not occur and the danger of capacitance coupling is significantly increased. Therefore, metal ports should never be used with a plastic cuff. The danger of capacitance coupling can be prevented by using entirely plastic ports.

Figure 4.20 Capacitance coupling during laparoscopic surgery. Reproduced with permission from Royal College of Surgeons of England. *The intercollegiate basic surgical skills course participants handbook*, edns 1–4. London: RCS.

THE PRINCIPLES OF LIGASURE

'Ligasure' tissue fusion technology is a vessel sealing system that is used in both open and laparoscopic surgery. It actually fuses the vessel walls to create a permanent seal and is in wide use in a range of surgical specialties, including gynaecology, colorectal, urology and general surgery. It uses a combination of pressure and energy to create vessel fusion which can withstand up to three times the normal systolic pressure.

New technology of the ligasure system involves advanced monopolar technology that uses the body's own collagen and elastin to both seal and divide, allowing surgeons to reduce instrument handling when dissecting, ligating and grasping – a valuable asset particularly during laparoscopic surgery. The feedback sensing technology incorporated in the instrument is designed to manage the energy delivery in a precise manner and results in an automatic discontinuation of energy once the seal is complete, thus removing any concern that the surgeon has to use guesswork as to when the seal is complete. The newer instruments actively monitor tissue impedance and provide a real-time adjustment of the energy being delivered. Using this technology, ligasure can seal vessels of up to 7 mm diameter, with an average seal time of 2–4 seconds, as well as pedicles, tissue bundles and lymphatics with a consistent controlled and predictable effect on tissue, including less dessication.

Therefore, the new Ligasure Advance™ can dissect, seal and divide and was designed to be the only tool that a surgeon would need. However, it is relatively expensive to use compared to some of the competing technology.

THE PRINCIPLES OF THE 'HARMONIC SCALPEL'

The harmonic scalpel is an instrument that uses ultrasound technology to cut tissues while simultaneously sealing them. It

utilises a hand-held ultrasound transducer and scalpel which is controlled by a hand switch or foot pedal. During use, the scalpel vibrates in the 20 000–50 000 Hz range and cuts through tissues, effecting haemostasis by sealing vessels and tissues by means of protein denaturation caused by vibration rather than heat (in a similar manner to whisking an egg white). It provides cutting precision, even through thickened scar tissue, and visibility is enhanced due to less smoke being created by this system during use compared to routine electrosurgery. However, the harmonic scalpel does take longer to cut and coagulate tissues than diathermy, and while diathermy can be used to coagulate a bleeding vessel at any time, the harmonic scalpel can only coagulate as it cuts. It is claimed that patients experience less swelling, bleeding and bruising after the use of the harmonic scalpel than when a conventional scalpel is used, and blood vessels are sealed with a much lower temperature than conventional diathermy and so there is less thermal damage to adjacent tissue, with less charring and dessication. Furthermore, it is suggested that the use of the harmonic scalpel reduces operative time and recovery is thus enhanced. Currently, the harmonic scalpel is in common use during laparoscopic procedures, as well as open surgery, such as thyroidectomy and several plastic surgery operations, e.g. cosmetic breast surgery.

Surgical infection

LEARNING OBJECTIVES

To understand:

- The factors that determine whether a wound will become infected
- The classification of sources of infection and their severity
- The indications for and choice of prophylactic antibiotics
- The characteristics of the common surgical pathogens and their sensitivities
- The spectrum of commonly used antibiotics in surgery and the principles of therapy
- The misuse of antibiotic therapy with the risk of resistance (such as methicillin-resistant *Staphylococcus aureus* (MRSA)) and emergence (such as *Clostridium difficile* enteritis)

To learn:

- Koch's postulates
- The management of abscesses

To appreciate:

- The importance of aseptic and antiseptic techniques and delayed primary or secondary closure in contaminated wounds

To be aware of:

- The causes of reduced resistance to infection (host response)

To know:

- The definitions of infection, particularly at surgical sites
- What basic precautions to take to avoid surgically relevant health care-associated infections

PHYSIOLOGY AND PRESENTATION

Background

Surgical infection, particularly surgical site infection (SSI), has always been a major complication of surgery and trauma and has been documented for 4000–5000 years. The Egyptians had some concepts about infection as they were able to prevent putrefaction, testified by mummification skills. Their medical papyri also describe the use of salves and antiseptics to prevent SSIs. This 'prophylaxis' had also been known earlier by the Assyrians, although less well documented. It was described again independently by the Greeks. The Hippocratic teachings described the use of antimicrobials, such as wine and vinegar, which were widely used to irrigate open, infected wounds before delayed primary or secondary wound closure. A belief common to all these civilisations, and indeed even later to the Romans, was that, whenever pus localised in an infected wound, it needed to be drained.

Galen recognised that this localisation of infection (suppuration) in wounds, inflicted in the gladiatorial arena, often heralded recovery, particularly after drainage (*pus bonum et laudabile*). Sadly, this dictum was misunderstood by many later healers, who thought that it was the production of pus that was desirable. Until well into the Middle Ages, some practitioners promoted suppuration in wounds by the application of noxious substances, including faeces, in the misguided belief that healing could not occur without pus formation. Theodor of Cervia, Ambroise Paré and Guy de Chauliac observed that clean wounds, closed primarily, could heal without infection or suppuration.

The understanding of the causes of infection came in the nineteenth century. Microbes had been seen under the microscope, but Koch laid down the first definition of infective disease (Koch's postulates; Summary box 5.1). Koch's postulates do not cover every eventuality though. Organisms of low virulence may not cause disease in normal hosts but may be responsible for disease in immunocompromised hosts. Some hosts may develop

Hippocrates was a Greek physician, and by common consent 'The Father of Medicine'. He was born on the Greek island of Cos off Turkey about 460 bc and probably died in 375 bc. He lived to be about 109 years of age in an era when the life expectancy was about 32 years.

Galen, 130–200, a Roman physician, who commenced practice as surgeon to the gladiators at Pergamum (now Bregama in Turkey) and later became personal physician to the Emperor Marcus Aurelius and to two of his successors. He was a prolific writer on many subjects, among them anatomy, medicine, pathology and philosophy. His work affected medical thinking for 15 centuries after his death. [Gladiator is Latin for 'swordsmen'.]

Theodor of Cervia. Theodor, 1210–1298, who was Bishop of Cervia, published a book on surgery about 1267.

Ambroise Paré, 1510–1590, a French military surgeon, who also worked at the Hotel Dieu, Paris, France.

Guy de Chauliac, ?1298–1368, was physician and chaplain to Pope Clement VI at Avignon, France. He was the author of *Chirurgia Magna* which was published about 1363.

subclinical disease and yet still be a carrier of the organism capable of infecting others. Also, not every organism that causes disease can be grown in culture, the commonly quoted one being *Mycobacterium leprae* which causes leprosy.

Summary box 5.1

Koch's postulates proving whether a given organism is the cause of a given disease

- It must be found in every case
- It should be possible to isolate it from the host and grow it in culture
- It should reproduce the disease when injected into another healthy host
- It should be recovered from an experimentally infected host

The Austrian obstetrician Ignac Semmelweis showed that puerperal sepsis could be reduced from over 10 per cent to under 2 per cent by the simple act of hand washing between cases, particularly between post-mortem examinations and the delivery suite. He was ignored by his contemporaries.

Louis Pasteur recognised through his germ theory that micro-organisms were responsible for infecting humans and causing disease. Joseph Lister applied this knowledge to the reduction of colonising organisms in compound fractures by using antiseptics. The principles of antiseptic surgery were soon enhanced with aseptic surgery at the turn of the century. As well as killing the bacteria on the skin before surgical incision (antiseptic technique), the conditions under which the operation was performed were kept free of bacteria (aseptic technique). This technique is still employed in modern operating theatres.

The concept of a 'magic bullet' (*Zauberkegel*) that could kill microbes but not their host became a reality with the discovery of sulphonamide chemotherapy in the mid-twentieth century. The discovery of the antibiotic penicillin is attributed to Alexander Fleming in 1928, but it was not isolated for clinical use until 1941 by Florey and Chain. The first patient to receive penicillin was Police Constable Alexander in Oxford. He scratched the side of his mouth while pruning roses and developed abscesses of the face and eyes leading to a severe staphylococcal bacteraemia. He responded to treatment, made a partial recovery before the penicillin ran out, then relapsed and died. Since then, there has been a proliferation of antibiotics with broad-spectrum activity and antibiotics today remain the mainstay of antimicrobial therapy.

Many staphylococci today have become resistant to penicillin. Often bacteria develop resistance through the acquisition of β -lactamases, which break up the β -lactam ring present in

the molecular structure of many antibiotics. The acquisition of extended spectrum β -lactamases (ESBLs) is an increasing concern in some Gram-negative organisms that cause urinary tract infections because it is difficult to find an antibiotic effective against them. In addition, there is increasing concern about the rising resistance of many other bacteria to antibiotics, in particular the emergence of methicillin-resistant *Staphylococcus aureus* (MRSA) and glycopeptide-resistant enterococci (GRE), which are also relevant in general surgical practice.

The introduction of antibiotics for prophylaxis and for treatment, together with advances in anaesthesia and critical care medicine, has made possible surgery that would not previously have been considered. Faecal peritonitis is no longer inevitably fatal, and incisions made in the presence of such contamination can heal primarily without infection in 80–90 per cent of patients with appropriate antibiotic therapy. Despite this, it is common practice in many countries to delay wound closure in patients in whom the wound is known to be contaminated or dirty. Waiting for the wound to granulate and then performing a delayed primary or secondary closure may be considered a better option (Summary box 5.2).

Summary box 5.2

Advances in the control of infection in surgery

- Aseptic operating theatre techniques have enhanced the use of antiseptics
- Antibiotics have reduced postoperative infection rates after elective and emergency surgery
- Delayed primary, or secondary, closure remains useful in contaminated wounds

Surgical site infection in patients who have contaminated wounds, who are immunosuppressed or undergoing prosthetic surgery, is now the exception rather than the rule since the introduction of prophylactic antibiotics. The evidence for this is of the highest level. The value of prophylactic antibiotics in clean, non-prosthetic surgery remains controversial, although SSI rates after such surgery is high when judged by close, unbiased, post-discharge surveillance, using strict definitions.

PHYSIOLOGY

Microorganisms are normally prevented from causing infection in tissues by intact epithelial surfaces, most notably the skin. These surfaces are broken down by trauma or surgery. In addition to these mechanical barriers, there are other protective mechanisms, which can be divided into:

- **chemical:** low gastric pH
- **humoral:** antibodies, complement and opsonins
- **cellular:** phagocytic cells, macrophages, polymorphonuclear cells and killer lymphocytes.

All these natural mechanisms may be compromised by surgical intervention and treatment.

Reduced resistance to infection has several causes (Summary box 5.3).

Joseph Lister (Lord Lister), 1827–1912, Professor of Surgery, Glasgow (1860–1869), Edinburgh (1869–1877) and King's College Hospital, London, UK (1877–1892). He was the first to show the relation between microbial infection and surgical sepsis. He associated Pasteur's observations on fermentation with sepsis and, using a carbolic dressing and spray, introduced the 'antiseptic principle' which revolutionised surgery. Asepsis in surgery has now replaced antiseptics but the dangers of sepsis are still very much with us.

Sir Ernst Boris Chain, Professor of Biochemistry, Imperial College, London, UK. Fleming, Florey and Chain shared the 1945 Nobel Prize for Physiology or Medicine for their work on penicillin.

Antony van Leeuwenhoek of Delft, The Netherlands, invented the microscope, and was the first to see bacteria in 1875. He himself made more than 400 microscopes.

Robert Koch, 1843–1910, Professor of Hygiene and Bacteriology, Berlin, Germany, stated his 'Postulates' in 1882.

Ignac Semmelweis, 1818–1865, Professor of Obstetrics, Budapest, Hungary.

Louis Pasteur, 1822–1895, was a French chemist, bacteriologist and immunologist who was Professor of Chemistry at the Sorbonne, Paris, France.

Sir Alexander Fleming, 1881–1955, Professor of Bacteriology, St Mary's Hospital, London, UK, discovered *Penicillium notatum* in 1928.

Howard Walter Florey (Lord Florey of Adelaide), 1898–1968, Professor of Pathology, The University of Oxford, Oxford, UK.

Summary box 5.3**Causes of reduced host resistance to infection**

- Metabolic: malnutrition (including obesity), diabetes, uraemia, jaundice
- Disseminated disease: cancer and acquired immunodeficiency syndrome (AIDS)
- Iatrogenic: radiotherapy, chemotherapy, steroids

Host response is weakened by malnutrition, which can be recognised clinically, and most easily, as recent rapid weight loss that can be present even in the presence of obesity. Metabolic diseases such as diabetes mellitus, uraemia and jaundice, disseminated malignancy and acquired immune deficiency syndrome (AIDS) are other contributors to infection and a poor healing response, as are iatrogenic causes including the immunosuppression caused by radiotherapy, chemotherapy or steroids (Summary box 5.4, and Figures 5.1 and 5.2).

When enteral feeding is suspended during the perioperative period, and particularly with underlying disease such as cancer, immunosuppression, shock or sepsis, bacteria (particularly aerobic Gram-negative bacilli) tend to colonise the normally sterile upper gastrointestinal tract. They may then translocate to the mesenteric nodes and cause the release of endotoxins (lipopolysaccharide in bacterial cell walls), which can be one cause of a harmful systemic inflammatory response through the excessive release of proinflammatory cytokines and activation of macrophages (Figure 5.3). In the circumstances of reduced host resistance to infection, microorganisms that are not normally pathogenic may start to behave as pathogens. This is known as opportunistic infection. Opportunistic infection with fungi is an example, particularly when prolonged and changing antibiotic regimens have been used.

The chance of developing an SSI after surgery is also determined by the pathogenicity of the organisms present and by the size of the bacterial inoculum. Devitalised tissue, excessive dead space or haematoma, all the results of poor surgical technique, increase the chances of infection. The same applies to foreign materials of any kind, including sutures and drains. If there is a silk suture in tissue, the critical number of organisms needed to start an infection is reduced logarithmically. Silk should not

Figure 5.1 Major wound infection and delayed healing presenting as a faecal fistula in a patient with Crohn's disease.

Figure 5.2 Delayed healing relating to infection in a patient on high-dose steroids.

Summary box 5.4**Risk factors for increased risk of wound infection**

- Malnutrition (obesity, weight loss)
- Metabolic disease (diabetes, uraemia, jaundice)
- Immunosuppression (cancer, AIDS, steroids, chemotherapy and radiotherapy)
- Colonisation and translocation in the gastrointestinal tract
- Poor perfusion (systemic shock or local ischaemia)
- Foreign body material
- Poor surgical technique (dead space, haematoma)

be used to close skin as it causes suture abscesses for this reason. These principles are important to an understanding of how best to prevent infection in surgical practice (Summary box 5.5).

Figure 5.3 Gut failure, colonisation and translocation related to the development of multiple organ dysfunction syndrome (MODS) and systemic inflammatory response syndrome (SIRS). IL, interleukin; TNF, tumour necrosis factor.

Summary box 5.5**Factors that determine whether a wound will become infected**

- Host response
- Virulence and inoculum of infective agent
- Vascularity and health of tissue being invaded (including local ischaemia as well as systemic shock)
- Presence of dead or foreign tissue
- Presence of antibiotics during the 'decisive period'

There is a delay before host defences can become mobilised after a breach in an epithelial surface, whether caused by trauma or surgery. The acute inflammatory, humoral and cellular defences take up to 4 hours to be mobilised. This is called the 'decisive period', and it is the time when the invading bacteria may become established in the tissues. Strategies aimed at preventing infection from taking a hold become ineffective after this time period. It is therefore logical that prophylactic antibiotics should be given to cover this period and that they could be decisive in preventing an infection from developing. The tissue levels of antibiotics should be above the minimum inhibitory concentration (MIC_{90}) for the pathogens likely to be encountered.

Local and systemic presentation

The infection of a wound can be defined as the invasion of organisms through tissues following a breakdown of local and systemic host defences, leading to cellulitis, lymphangitis, abscess and bacteraemia. The infection of most surgical wounds is referred to as superficial surgical site infection (SSSI). The other categories include deep SSI (infection in the deeper musculofascial layers) and organ space infection (such as an abdominal abscess after an anastomotic leak).

Pathogens resist host defences by releasing toxins, which favour their spread, and this is enhanced in anaerobic or frankly necrotic wound tissue. *Clostridium perfringens*, which is responsible for gas gangrene, releases proteases such as hyaluronidase, lecithinase and haemolysin, which allow it to spread through the tissues. Resistance to antibiotics can be acquired by previously sensitive bacteria by transfer through plasmids.

The human body harbours approximately 10^{14} organisms. They can be released into tissues by surgery, contamination being most severe when a hollow viscus perforates (e.g. faecal peritonitis following a diverticular perforation). Any infection that follows surgery may be termed primary or secondary (Summary box 5.6).

Summary box 5.6**Classification of sources of infection**

- Primary: present in or on the host and so acquired from an endogenous source (such as an SSSI following contamination of the wound from a perforated appendix)
- Secondary or exogenous (HAI): acquired from a source outside the body such as the operating theatre (inadequate air filtration, poor antisepsis) or the ward (e.g. poor hand washing compliance)

Infection that follows surgery or admission to hospital is termed health care-associated infection (HAI). There are four main groups: respiratory infections (including ventilator-associated pneumonia), urinary tract infections (mostly related to urinary catheters), bacteraemia (mostly related to indwelling vascular catheters) and SSIs.

MAJOR AND MINOR SURGICAL SITE INFECTIONS

A major SSI is defined as a wound that either discharges significant quantities of pus spontaneously or needs a secondary procedure to drain it (Figure 5.4). The patient may have systemic signs, such as tachycardia, pyrexia and a raised white count (Summary box 5.7).

Summary box 5.7**Major wound infections**

- Significant quantity of pus
- Delayed return home
- Patients are systemically ill

Minor wound infections may discharge pus or infected serous fluid but should not be associated with excessive discomfort, systemic signs or delay in return home (Figure 5.5). The differentiation between major and minor and the definition of SSI is important in audit or trials of antibiotic prophylaxis. There are scoring systems for the severity of wound infection, which are particularly useful in surveillance and research. Examples are the Southampton (Table 5.1) and ASEPSIS systems (Table 5.2).

Accurate surveillance can only be achieved using trained, unbiased and blinded assessors. Most include surveillance for a 30-day postoperative period. The US Centers for Disease Control (CDC) definition insists on a 30-day follow-up period for non-prosthetic surgery and one year after implanted hip and knee surgery.

Types of localised infection**Abscess**

An abscess presents all the clinical features of acute inflamma-

Figure 5.4 Major wound infection with superficial skin dehiscence.

Figure 5.5 Minor wound infection that settled spontaneously without antibiotics.

tion originally described by Celsus: **calor** (heat), **rubor** (redness), **dolour** (pain) and **tumour** (swelling). To these can be added **functio laesa** (loss of function: if it hurts, the infected part is not used). They usually follow a puncture wound of some kind, which may have been forgotten, as well as surgery, but can be metastatic in all tissues following bacteraemia.

Pyogenic organisms, predominantly *Staphylococcus aureus*, cause tissue necrosis and suppuration. Pus is composed of dead and dying white blood cells that release damaging cytokines, oxygen free radicals and other molecules. An abscess is surrounded by an acute inflammatory response composed of a fibrinous exudate, oedema and the cells of acute inflammation. Granulation tissue (macrophages, angiogenesis and fibroblasts) forms later around the suppurative process and leads to collagen deposition. If it is not drained or resorbed completely, a chronic abscess may result. If it is partly sterilised with antibiotics, an antibioma may form.

Abscesses contain hyperosmolar material that draws in fluid. This increases the pressure and causes pain. If they spread, they usually track along planes of least resistance and point towards the skin. Wound abscesses may discharge spontaneously by tracking to a surface, but may need drainage through a surgical incision. Most abscesses relating to surgical wounds take 7–10 days to form after surgery. As many as 75 per cent of SSIs present

after the patient has left hospital and may thus be overlooked by the surgical team. Their cost and management, which may be inadequate, is transferred to primary care (Summary box 5.8).

Table 5.1 Southampton wound grading system.

Grade	Appearance
0	Normal healing
I	Normal healing with mild bruising or erythema
Ia	Some bruising
Ib	Considerable bruising
Ic	Mild erythema
II	Erythema plus other signs of inflammation
IIa	At one point
IIb	Around sutures
IIc	Along wound
IId	Around wound
III	Clear or haemoserous discharge
IIIa	At one point only (≤ 2 cm)
IIIb	Along wound (> 2 cm)
IIIC	Large volume
IIId	Prolonged (> 3 days)
Major complication	
IV	Pus
IVa	At one point only (≤ 2 cm)
IVb	Along wound (> 2 cm)
V	Deep or severe wound infection with or without tissue breakdown; haematoma requiring aspiration

Table 5.2 The ASEPSIS wound score.

Criterion	Points
A dditional treatment	0
Antibiotics for wound infection	10
Drainage of pus under local anaesthesia	5
Debridement of wound under general anaesthesia	10
S erous discharge ^a	Daily 0–5
E rythema ^a	Daily 0–5
P urulent exudate ^a	Daily 0–10
S eparation of deep tissues ^a	Daily 0–10
I solation of bacteria from wound	10
S tay as inpatient prolonged over 14 days as result of wound infection	5

^a Scored for 5 of the first 7 days only, the remainder being scored if present in the first two months.

Summary box 5.8**Abscesses**

- Abscesses need drainage
- Modern imaging techniques may allow guided aspiration
- Antibiotics are indicated if the abscess is not localised (e.g. evidence of cellulitis) or the cavity is not left open to drain freely
- Healing by secondary intention is encouraged

Abscess cavities need cleaning out after incision and drainage and are traditionally encouraged to heal by secondary intention. When the cavity is left open to drain freely, there is no need for antibiotic therapy as well. Antibiotics should be used if the abscess cavity is closed after drainage, but the cavity should not be closed if there is any risk of retained loculi or foreign material. Thus a perianal abscess can be incised and drained, the walls curetted and the skin closed with good results using appropriate antibiotic therapy, but a pilonidal abscess has a higher recurrence risk after such treatment because a nidus of hair may remain in the subcutaneous tissue adjacent to the abscess. Some small breast abscesses can be managed by simple needle aspiration of the pus and antibiotic therapy.

Persistent chronic abscesses may lead to sinus or fistula formation. In a chronic abscess, lymphocytes and plasma cells are seen. There is tissue sequestration and later calcification may occur. Certain organisms are associated with chronicity, sinus and fistula formation. Common ones are *Mycobacterium* and *Actinomyces*. They should not be forgotten when these complications occur and persist.

Perianastomotic contamination may be the cause of an abscess but, in the abdomen, abscesses are more usually the result of anastomotic leakage. An abscess in a deep cavity, such as the pleura or peritoneum, may be difficult to diagnose or locate even when there is strong clinical suspicion that it is present (Figure 5.6). Plain or contrast radiographs may not be helpful, but ultrasonography, computed tomography (CT), magnetic resonance imaging (MRI) and isotope scans are all useful and may allow guided aspiration without the need for surgical intervention.

Cellulitis and lymphangitis

Cellulitis is the non-suppurative invasive infection of tissues. There is poor localisation in addition to the cardinal signs of inflammation. Spreading infection presenting in surgical practice is typically caused by organisms such as β -haemolytic streptococci (Figure 5.7), staphylococci (Figure 5.8) and *C. perfringens*. Tissue destruction, gangrene and ulceration may follow, which are caused by release of proteases.

Systemic signs (the old-fashioned term toxaemia) are common, with chills, fever and rigors. These follow the release of toxins into the circulation, which stimulate a cytokine-mediated systemic inflammatory response even though blood cultures are negative.

Lymphangitis is part of a similar process and presents as painful red streaks in affected lymphatics. Cellulitis is usually located at the point of injury and subsequent tissue infection. Lymphangitis is often accompanied by painful lymph node groups in the related drainage area (Summary box 5.9).

Summary box 5.9**Cellulitis and lymphangitis**

- Non-suppurative, poorly localised
- Commonly caused by streptococci, staphylococci or clostridia
- Blood cultures are often negative

SYSTEMIC INFLAMMATORY RESPONSE SYNDROME AND MULTIPLE ORGAN DYSFUNCTION SYNDROME

Systemic inflammatory response syndrome (SIRS) is a systemic manifestation of sepsis, although the syndrome may also be caused by multiple trauma, burns or pancreatitis without infection. Serious infection, such as secondary peritonitis, may lead to SIRS through the release of lipopolysaccharide endotoxin from the walls of dying Gram-negative bacilli (mainly *Escherichia coli*) or other bacteria or fungi. This and other toxins stimulate the release of cytokines from macrophages (Figure 5.3). SIRS should not be confused with bacteraemia although the two may coexist (see Table 5.3).

Septic manifestations and multiple organ dysfunction syndrome (MODS) in SIRS are mediated by the release of proinflammatory cytokines such as interleukin-1 (IL-1) and tumour necrosis factor alpha (TNF α). These cytokines stimulate neu-

Figure 5.6 Plain radiograph showing a subphrenic abscess with a gas/fluid level (white arrow). Gastrografin is seen leaking from the oesophagojejunal anastomosis (after gastrectomy) towards the abscess (black arrow).

Figure 5.7 Streptococcal cellulitis of the leg following a minor puncture wound.

trophil adhesion to endothelial surfaces adjacent to the source of infection and cause them to migrate through the blood vessel wall by chemotaxis. A respiratory burst occurs within such activated neutrophils, releasing lysosomal enzymes, oxidants and free radicals, which are involved in killing the invading bacteria but which may also damage adjacent cells. Coagulation, complement and fibrinolytic pathways are also stimulated as part of the normal inflammatory response. This response is usually beneficial to the host and is an important aspect of normal tissue repair and wound healing. In the presence of severe sepsis or bacteraemia, this response may become harmful to the host if it occurs in excess, when it is known as SIRS. There are high circulating levels of cytokines and activated neutrophils which stimulate fever, tachycardia and tachypnoea. The activated neutrophils adhere to vascular endothelium in key organs remote from the source of infection and damage it, leading to increased vascular permeability, which in turn leads to cellular damage within the organs, which become dysfunctional and give rise to the clinical picture of MODS. In its most severe form, MODS may progress into multiple system organ failure (MSOF). Respiratory, cardiac, intestinal, renal and liver failure ensue in combination with

Figure 5.8 Staphylococcal cellulitis of the face and orbit following severe infection of an epidermoid cyst of the scalp.

circulatory failure and shock. In this state, the body's resistance to infection is reduced and a vicious cycle develops where the more organs that fail, the more likely it becomes that death will follow despite all that a modern intensive care unit can do for organ support (Summary box 5.10).

Table 5.3 Definitions of systemic inflammatory response syndrome (SIRS) and sepsis.

SIRS

Two of:

- hyperthermia ($>38^{\circ}\text{C}$) or hypothermia ($<36^{\circ}\text{C}$)
- tachycardia ($>90/\text{min}$, no β -blockers) or tachypnoea ($>20/\text{min}$)
- white cell count $>12 \times 10^9/\text{l}$ or $<4 \times 10^9/\text{l}$

Sepsis is SIRS with a documented infection

Severe sepsis or sepsis syndrome is sepsis with evidence of one or more organ failures (respiratory (acute respiratory distress syndrome), cardiovascular (septic shock follows compromise of cardiac function and fall in peripheral vascular resistance), renal (usually acute tubular necrosis), hepatic, blood coagulation systems or central nervous system)

Summary box 5.10

Definitions of infected states

- SSI is an infected wound or deep organ space
- SIRS is the body's systemic response to severe infection
- MODS is the effect that SIRS produces systemically
- MSOF is the end stage of uncontrolled MODS

Bacteraemia and sepsis

Bacteraemia is unusual following superficial SSIs but common after anastomotic breakdown (deep space SSI). It is usually transient and can follow procedures undertaken through infected tissues (particularly instrumentation in infected bile or urine). It may also occur through bacterial colonisation of indwelling intravenous cannulae. Bacteraemia is important when a prosthe-

sis has been implanted, as infection of the prosthesis can occur. Sepsis accompanied by MODS may follow anastomotic breakdown. Aerobic Gram-negative bacilli are mainly responsible, but *S. aureus* and fungi may be involved, particularly after the use of broad-spectrum antibiotics (Summary box 5.11).

Summary box 5.11

Bacteraemia and sepsis

- Sepsis is common after anastomotic breakdown
- Bacteraemia is dangerous if the patient has a prosthesis
- Sepsis may be associated with MODS

Specific wound infections

Gas gangrene

This is caused by *C. perfringens*. These Gram-positive, anaerobic, spore-bearing bacilli are widely found in nature, particularly in soil and faeces. This is relevant to military and traumatic surgery and colorectal operations. Patients who are immunocompromised, diabetic or have malignant disease are at greater risk, particularly if they have wounds containing necrotic or foreign material, resulting in anaerobic conditions. Military wounds provide an ideal environment as the kinetic energy of high-velocity missiles or shrapnel causes extensive tissue damage. The cavitation which follows passage of a missile through the tissues causes a 'sucking' entry wound, leaving clothing and environmental soiling in the wound in addition to devascularised tissue. Gas gangrene wound infections are associated with severe local wound pain and crepitus (gas in the tissues, which may also be noted on plain radiographs). The wound produces a thin, brown, sweet-smelling exudate, in which Gram staining will reveal bacteria. Oedema and spreading gangrene follow the release of collagenase, hyaluronidase, other proteases and alpha toxin. Early systemic complications with circulatory collapse and MSOF follow if prompt action is not taken (Summary box 5.12).

Antibiotic prophylaxis should always be considered in patients at risk, especially when amputations are performed for peripheral vascular disease with open necrotic ulceration. Once gas gangrene infection is established, large doses of intravenous penicillin and aggressive debridement of affected tissues are required.

Summary box 5.12

Gas gangrene

- Caused by *C. perfringens*
- Gas and smell are characteristic
- Immunocompromised patients are most at risk
- Antibiotic prophylaxis is essential when performing amputations to remove dead tissue

Clostridium tetani

This is another anaerobic, terminal spore-bearing, Gram-positive bacterium that can cause tetanus following implantation into

tissues or a wound (which may have been trivial or unrecognised and forgotten). The spores are widespread in soil and manure, and so the infection is more common in traumatic civilian or military wounds. The signs and symptoms of tetanus are mediated by the release of the exotoxin tetanospasmin, which affects myoneural junctions and the motor neurones of the anterior horn of the spinal cord. A short prodromal period, which has a poor prognosis, leads to spasms in the distribution of the short motor nerves of the face followed by the development of severe generalised motor spasms including opisthotonus, respiratory arrest and death. A longer prodromal period of 4–5 weeks is associated with a milder form of the disease. The entry wound may show a localised small area of cellulitis; exudate or aspiration may give a sample that can be stained to show the presence of Gram-positive rods. Prophylaxis with tetanus toxoid is the best preventative treatment but, in an established infection, minor debridement of the wound may need to be performed and antibiotic treatment with benzylpenicillin provided in addition. Relaxants may also be required, and the patient may require ventilation in severe forms, which may be associated with a high mortality. The use of antitoxin using human immunoglobulin ought to be considered for both at-risk wounds and established infection.

The toxoid is a formalin-attenuated vaccine and should be given in three separate doses to give protection for a five-year period, after which a single five-yearly booster confers immunity. It should be given to all patients with open traumatic wounds who are not immunised. At-risk wounds are those that present late, when there is devitalisation of tissue or when there is soiling. For these wounds, a booster of toxoid should be given or, if not immunised at all, a three-dose course, together with prophylactic benzylpenicillin; however, the use of antitoxin is controversial because of the risk of toxicity and allergy.

Synergistic spreading gangrene (synonym: subdermal gangrene, necrotising fasciitis)

This condition is not caused by clostridia. A mixed pattern of organisms is responsible: coliforms, staphylococci, *Bacteroides* spp., anaerobic streptococci and peptostreptococci have all been implicated, acting in synergy. Abdominal wall infections are known as Meleney's synergistic hospital gangrene and scrotal infection as Fournier's gangrene (Figure 5.9). Patients are almost always immunocompromised with conditions such as diabetes mellitus. The wound initiating the infection may have been minor, but severely contaminated wounds are more likely to be the cause. Severe wound pain, signs of spreading inflammation with crepitus and smell are all signs of the infection spreading. Untreated, it will lead to widespread gangrene and MSOF. The subdermal spread of gangrene is always much more extensive than appears from initial examination. Broad-spectrum antibiotic therapy must be combined with aggressive circulatory support. Locally, there should be wide excision of necrotic tissue and laying open of affected areas. The debridement may need to be extensive, and patients who survive may need large areas of skin grafting.

TREATMENT OF SURGICAL INFECTION

Now that patients are discharged more quickly after surgery and many procedures are performed as day cases, many SSIs are

missed by the surgical team unless they undertake a prolonged and carefully audited follow up with primary care doctors. Suppurative wound infections take 7–10 days to develop, and even cellulitis around wounds caused by invasive organisms (such as the β -haemolytic *Streptococcus*) takes 3–4 days to develop. Major surgical infections with systemic signs (Figure 5.10), evidence of spreading infection, cellulitis or bacteraemia need treatment with appropriate antibiotics. The choice may need to be empirical initially but is best based on culture and sensitivities of isolates harvested at surgery. Although the identification of organisms in surgical infections is necessary for audit and wound surveillance purposes, it is usually 2–3 days before sensitivities are known (Figures 5.11 and 5.12). It is illogical to withhold antibiotics until these are available but, if clinical response is poor by the time sensitivities are known, then antibiotics can be changed. This is unusual if the empirical choice of antibiotics is sensible; change of antibiotics promotes resistance and risks complications, such as *C. difficile* enteritis.

If an infected wound is under tension, or there is clear evidence of suppuration, sutures or clips need to be removed, with curettage if necessary, to allow pus to drain adequately. There

is no evidence that subcuticular continuous skin closure contributes to or prevents suppuration. In severely contaminated wounds, such as an incision made for drainage of an abscess, it is logical to leave the skin open. Delayed primary or secondary suture can be undertaken when the wound is clean and granulating (Figures 5.13 and 5.14). Leaving wounds open after a ‘dirty’ operation, such as laparotomy for faecal peritonitis, is not practised as widely in the UK as in the US or mainland Europe (Summary box 5.13).

Summary box 5.13

Surgical incisions through infected or contaminated tissues

- When possible, tissue or pus for culture should be taken before antibiotic cover is started
- The choice of antibiotics is empirical until sensitivities are available
- Wounds are best managed by delayed primary or secondary closure

Figure 5.9 A classic presentation of Fournier's gangrene of the scrotum with 'shameful exposure of the testes' following excision of the gangrenous skin.

Figure 5.11 Mixed streptococcal infection of a skin graft with very poor 'take'.

Figure 5.12 After 5–6 days of antibiotics, the infection shown in Figure 5.11 is under control, and the skin grafts are clearly viable.

When taking pus from infected wounds, specimens should be sent fresh for microbiological culture. Swabs should be placed in transport medium, but the larger the volume of pus sent, the more likely is the accurate identification of the organism involved. Providing the microbiologist with as much information as possible and discussing the results with him or her gives the best chance of the most appropriate antibiotic treatment. If bacteraemia is suspected, but results are negative, then repeat specimens for blood culture may need to be taken.

A rapid report on infective material can be based on an immediate Gram stain. Aerobic and anaerobic culture on conventional media allows sensitivities to be assessed by disc diffusion. Measurements of minimum inhibitory antibiotic concentrations (MIC_{90} in mg/L), together with measurements of endotoxin and cytokine levels, are usually only needed for research studies.

Figure 5.13 Skin layers left open to granulate after laparotomy for faecal peritonitis. The wound is clean and ready for secondary closure.

Many dressings are now available for use in wound care. These are listed in Table 5.4. Polymeric films are used as incision drapes and also to cover sutured wounds, but are not indicated for use in wound infections. Agents that can be used to help debride open infected wounds and others to absorb excessive exudate or to encourage epithelialisation and the formation of granulation tissue are also listed (Figure 5.15). Most contribute to the ideal moist wound environment, and there are others that provide an antibacterial to the wound. There is now a plethora of dressings containing silver or povidone–iodine antiseptics, but the use of topical antibiotics should be avoided because of the risks of allergy and resistance. Topical antiseptics inhibit epithelial ingrowth and should only be used on superficial wounds for a short period to clear infection from heavily contaminated wounds.

Prophylaxis

Prophylactic antibiotics

If antibiotics are given to prevent infection after surgery or instrumentation, they should be used when local wound defences are not established (the decisive period). Ideally, maximal blood and tissue levels should be present at the time at which the first incision is made and before contamination occurs. Intravenous administration at induction of anaesthesia is optimal. In long operations or when there is excessive blood loss or when unexpected contamination occurs, antibiotics may be repeated at 4-hourly intervals during the surgery, as tissue antibiotic levels often fall faster than serum levels. There is no evidence that further doses of antibiotics after surgery are of any value in prophylaxis against infection and the practice can only encourage the development of antibiotic resistance. The choice of an antibiotic depends on the expected spectrum of organisms likely to be encountered, the cost and local hospital policies, which are based on experience of local resistance trends (Summary box 5.14).

Table 5.4 Surgical dressings.

Type	Name (example)	Indications and comments
Debriding agents	Benoxyl–benzoic acid Aserbine–benzoic acid Variclene–lactic acid	Used only in necrotic sloughing skin ulcers. Provide acidic environment. Claimed to enhance healing with debriding action
Enzymatic agents	Varidase–streptokinase/streptodornase	Activate fibrinolysis and liquefy pus on chronic skin ulcers
Bead dressings	Debrisan	Remove bacteria and excess moisture by capillary action in deep granulating wounds. Antimicrobials
	Iodosorb	May be added but with questionable topical benefit
	Other paste dressings	
Polymeric films	Opsite	Primary adhesive transparent dressing for sutured wounds or donor sites
	Bioclusive	
	Tegaderm	
Foams	Silastic (elastomer)	Elastomeric dressing can be shaped to fit deep cavities and granulating wounds. Absorbent and non-adherent
	Lyof foam	
	Allevyn	
Hydrogels	Geliperm	Maintain moist environment. Polymers can absorb exudate or antiseptics (but adding antiseptics is of doubtful benefit). Semi-permeable, allow gas exchange
	Intrasite	
Hydrocolloids	Comfeel	Complete occlusion. Promote epithelialisation and granulation tissue. Maintain moisture without gaseous exchange across them
	Granuflex	
Fibrous polymers	Kaltostat	Absorptive alginate dressings. Derived from natural (seaweed) source. Like polymeric hydrocolloids and hydrogels, they can be used to pack deep wounds
	Sorbisan	
Biological membranes	Porcine skin, amnion	Used for superficial chronic skin ulcers. No proven advantage
Simple miscellaneous	Gauzes: viscose/cotton with non-adherent coating (Melolin)	Simple absorptive dressings only used as secondary dressings to absorb exudate. Added antimicrobials probably confer no benefit. Added charcoal absorbents may reduce swelling. Relatively cheap but of questionable effectiveness
	Tulles: non-adherent paraffin impregnation	

Figure 5.14 Delayed primary closure of fasciotomy wound.

Table 5.5 Suggested prophylactic regimens for operations at risk.

Type of surgery	Organisms encountered	Prophylactic regimen suggested
Vascular	<i>Staphylococcus epidermidis</i> (or MRCNS) <i>S. aureus</i> (or MRSA) Aerobic Gram-negative bacilli (AGNB)	One dose of augmentin with or without gentamicin, vancomycin or rifampicin if MRCNS/MRSA a risk
Orthopaedic	<i>S. epidermidis/aureus</i>	One dose of augmentin
Oesophagogastric	Enterobacteriaceae Enterococci (including anaerobic/ viridans streptococci)	One dose of a second-generation cephalosporin and metronidazole in severe contamination
Biliary	Enterobacteriaceae (mainly <i>Escherichia coli</i>) Enterococci (including <i>Streptococcus faecalis</i>)	One dose of a second-generation cephalosporin
Small bowel	Enterobacteriaceae Anaerobes (mainly <i>Bacteroides</i>)	One dose of a second-generation cephalosporin with or without metronidazole
Appendix/colorectal	Enterobacteriaceae Anaerobes (mainly <i>Bacteroides</i>)	One dose of a second-generation cephalosporin (or gentamicin) with metronidazole (the use of oral, poorly absorbed antibiotics is controversial)

MRCNS, multiply resistant coagulase-negative staphylococci; MRSA, methicillin-resistant *Staphylococcus aureus*.

Summary box 5.14

Choice of antibiotics for prophylaxis

- Empirical cover against expected pathogens with local hospital guidelines
- Single-shot intravenous administration at induction of anaesthesia
- Repeat only during long operations or if there is excessive blood loss
- Continue as therapy if there is unexpected contamination or if a prosthetic is implanted in a patient with a septic source
- Benzylpenicillin should be used if *Clostridium* gas gangrene infection is a possibility
- Patients with heart valve disease or a prosthesis should be protected from bacteraemia caused by dental work, urethral instrumentation or visceral surgery

The use of the newer, broad-spectrum antibiotics for prophylaxis should be avoided. Table 5.5 gives some examples of prophylaxis that can be used in elective surgical operations.

Patients with known valvular disease of the heart (or with any implanted vascular or orthopaedic prosthesis) should have prophylactic antibiotics during dental, urological or open viscus surgery. Single doses of broad-spectrum penicillin, for example amoxicillin, orally or intravenously administered, are sufficient for dental surgery. In urological instrumentation, a single dose of gentamycin is often used.

Preoperative preparation

Short preoperative hospital stay lowers the risk of acquiring MRSA, multiply resistant coagulase-negative staphylococci (MRCNS) and other organisms and the acquisition of HAIs. Medical and nursing staff should always wash their hands after any patient contact. Alcoholic hand gels can act as a substitute for hand washing, but do not destroy the spores of *C. difficile*, which may cause pseudomembranous colitis, especially

in immunocompromised patients or those whose gut flora is suppressed by antibiotic therapy. Although the need for clean hospitals, emphasised by the media, is logical, the 'clean your hands campaign' is beginning to result in falls in the incidence of HAIs. Staff with open, infected skin lesions should not enter the operating theatre. Ideally, neither should patients, especially if they are having a prosthesis implanted. Antiseptic baths (usually chlorhexidine) are popular in Europe, but there is no hard evidence for their value in reducing wound infections. Preoperative skin shaving should be undertaken in the operating theatre immediately before surgery as the SSI rate after clean wound surgery may be doubled if it is performed the night before; minor skin injury enhances superficial bacterial colonisation. Cream depilation is messy and hair clipping is best, with the lowest rate of infection (Summary box 5.15).

Figure 5.15 Infected animal bite/wound of the upper thigh, treated by open therapy following virulent staphylococcal infection. Deep cavity wounds such as this can be debrided and kept moist with many of the modern dressings listed in Table 5.4.

Table 5.6 Classification of antiseptics commonly used in general surgical practice.

Name	Presentation	Uses	Comments
Chlorhexidine (Hibiscrub)	Alcoholic 0.5% Aqueous 4%	Skin preparation Skin preparation. Surgical scrub in dilute solutions in open wounds	Has cumulative effect. Effective against Gram-positive organisms and relatively stable in the presence of pus and body fluids
Povidone-iodine (Betadine)	Alcoholic 10% Aqueous 7.5%	Skin preparation Skin preparation. Surgical scrub in dilute solutions in open wounds	Safe, fast-acting, broad spectrum. Some sporicidal activity. Anti-fungal iodine is not free but combined with polyvinylpyrrolidone (povidone)
Cetrimide (Savlon)	Aqueous	Hand washing Instrument and surface cleaning	<i>Pseudomonas</i> spp. may grow in stored contaminated solutions. Ammonium compounds have good detergent action (surface-active agent)
Alcohols	70% ethyl, isopropyl	Skin preparation	Should be reserved for use as disinfectants
Hypochlorites	Aqueous preparations (Eusol, Milton, Chloramine T)	Instrument and surface cleaning (debriding agent in open wounds?)	Toxic to tissues
Hexachlorophane	Aqueous bisphenol	Skin preparation Hand washing	Has action against Gram-negative organisms

Summary box 5.15**Avoiding surgical site infections**

- Staff should always wash their hands between patients
- Length of patient stay should be kept to a minimum
- Preoperative shaving should be done immediately before surgery
- Antiseptic skin preparation should be standardised
- Attention to theatre technique and discipline
- Avoid hypothermia perioperatively and ensure supplemental oxygenation in recovery

Scrubbing and skin preparation

For the first operation of the day, aqueous antiseptics should be used for hand washing, and the scrub should include the nails. Subsequent scrubbing should merely involve washing to the elbows, as repeated extensive scrubbing releases more organisms than it removes.

One application of an alcoholic antiseptic is adequate for skin preparation of the operative site. This leads to a more than 95 per cent reduction in bacterial count. Antiseptics in common use are listed in Table 5.6.

Theatre technique and discipline also contribute to low infection rates. Numbers of staff in the theatre and movement in and out of theatre should be kept to a minimum. Careful and regular surveillance is needed to ensure the quality of theatre ventilation, instrument sterilisation and aseptic technique. Operator skill in gentle manipulation and dissection of tissues is much more difficult to audit, but dead spaces and haematomas should be avoided and the use of diathermy kept to a minimum. There is no evidence that drains, incision drapes or wound guards help to reduce wound infection.

There is the highest level of evidence-based medicine that the perioperative avoidance of hypothermia and supplemental oxygen during recovery can significantly reduce the rate of SSIs.

Postoperative care of wounds

Similar attention to standards is needed in the postoperative care of wounds. Secondary (exogenous) SSIs, as well as other HAIs, can be related to poor hospital standards. For example, outbreaks of MRSA infections are rare but serious. The presence of this organism in wounds, and the number of MRSA bacteraemias, can be a marker of inadequate postoperative wound care, and it can be very difficult and expensive to screen for, identify and eradicate.

Careful audit should lead to changes in practice, and follow up should ensure that audit loops are closed. It is critical that surgeons manage their own audit; league tables kept by non-medical or related personnel must be accurate. Scoring systems are useful in audit but, in general, have only been used in wound infection research (Tables 5.2 and 5.3). Nevertheless, accurate audit ought to involve the use of trained, blinded observers in post-discharge surveillance of all HAIs, using validated and reproducible definitions.

CLASSIFICATION OF SURGICAL WOUNDS**Potential for infection**

The best measure of wound contamination at the end of an operation is to sample tissue in the wound edge. The theoretical degree of contamination, proposed by the National Research Council (USA) over 40 years ago, relates well to infection rates (Table 5.7). When wounds are heavily contaminated or when an incision is made into an abscess, therapeutic antibiotics may be justified. In these cases, infection rates of more than 15 per cent are expected. There is undisputed evidence that prophylactic antibiotics are effective in clean-contaminated and contaminated operations. Infection rates after non-prosthetic clean surgery may be higher than expected when carefully audited by post-discharge surveillance. Breast surgery, for example, is associated with a high risk of infection, or wound complications, which may be interpreted

Figure 5.16 Streptococci.

Figure 5.17 Staphylococcal pus.

Table 5.7 Surgical site infection (SSI) rates relating to wound contamination.

Type of surgery	Infection rate (%)	Rate before prophylaxis
Clean (no viscus opened)	1–2	The same
Clean-contaminated (viscus opened, minimal spillage)	<10	Gastric surgery up to 30% Biliary surgery up to 20%
Contaminated (open viscus with spillage or inflammatory disease)	15–20	Variable but up to 60%
Dirty (pus or perforation, or incision through an abscess)	<40	Up to 60% or more

as a failure to heal and related to a high body mass index (BMI). The value of antibiotic prophylaxis is controversial in non-prosthetic clean surgery, with most trials showing no clear benefit.

BACTERIA INVOLVED IN SURGICAL INFECTION

Streptococci

Streptococci form chains and are Gram positive on staining (Figure 5.16). The most important is the β -haemolytic *Streptococcus*, which resides in the pharynx of 5–10 per cent of the population. In the Lancefield A–G carbohydrate antigens classification, it is the group A *Streptococcus*, also called *Streptococcus pyogenes*, that is the most pathogenic. It has the ability to spread, causing cellulitis, and to cause tissue destruction through the release of enzymes such as streptolysin, streptokinase and streptodornase.

Streptococcus faecalis is an enterococcus in Lancefield group D. It is often found in synergy with other organisms, as is the γ -haemolytic *Streptococcus* and *Peptostreptococcus*, which is an anaerobe.

Both *Streptococcus pyogenes* and *Streptococcus faecalis* may be involved in wound infection after large bowel surgery, but the α -haemolytic *Streptococcus viridans* is not associated with wound infections.

All the streptococci remain sensitive to penicillin and erythromycin. The cephalosporins are a suitable alternative in patients who are allergic to penicillin.

Staphylococci

Staphylococci form clumps and are Gram positive (Figure 5.17). *Staphylococcus aureus* is the most important pathogen in this group and is found in the nasopharynx of up to 15 per cent of the population. It can cause exogenous suppurative in wounds (and implanted prostheses). Strains resistant to antibiotics (e.g. MRSA) can cause epidemics and more severe infection. It is controversial but, if MRSA infection is found in a hospital, all doctors, nurses and patients may need to be swabbed so that carriers can be identified and treated. In parts of northern Europe, the prevalence of MRSA infections has been kept at very low levels using 'search and destroy' methods, which use these screening techniques and the isolation or treatment of carriers. Patients found to be positive on screening may be denied access to hospital. Some MRSA strains are now also resistant to vancomycin. Local policies on the management of MRSA depend on the prevalence of MRSA, the type of hospital or clinical specialty and the availability of facilities. Widespread swabbing, ward closures, isolation of patients and disinfection of wards all have to be carefully considered and involve all groups of practitioners. They may be expensive but necessary options.

Infections are usually suppurative and localised (see above under Abscess). Most hospital *Staphylococcus aureus* strains are now β -lactamase producers and are resistant to penicillin, but most strains (MRSA) remain sensitive to flucloxacillin, vancomycin, aminoglycosides, some cephalosporins and fusidic acid (used in osteomyelitis). There are several novel and innovative antibiotics becoming available that have high activity against resistant strains. Some have the advantage of good oral activity (linezolid), some have a wide spectrum (tigecycline), have good activity in bacteraemia (daptomycin) but are relatively expen-

The name *Eusol* is derived from Edinburgh University solution of lime.

Rebecca Graighill Lancefield, 1895–1981, an American bacteriologist, classified streptococci in 1933.

sive, and some have side effects involving marrow, hepatic and renal toxicity. Their use is justified but needs to be controlled by tight local policies and guidelines that involve clinical microbiologists.

Staphylococcus epidermidis (previously *Staphylococcus albus*), also known as coagulase-negative staphylococci (CNS), was regarded as a commensal but is now recognised as a major threat in prosthetic (vascular and orthopaedic) surgery and in indwelling vascular catheters. They can be multiply resistant (MRCNS) to many antibiotics and represent an important cause of HAI.

Clostridia

Clostridial organisms are Gram-positive, obligate anaerobes, which produce resistant spores (Figure 5.18). *C. perfringens* is the cause of gas gangrene, and *C. tetani* causes tetanus after implantation into tissues or a wound (see above under Specific wound infections).

C. difficile is the cause of pseudomembranous colitis. This is another HAI, now more common than the incidence of MRSA bacteraemia, which is caused by the overuse of antibiotics. The quinolones, such as ciprofloxacin, seem to be most implicated, but the inappropriate sequential use of several antibiotics puts patients most at risk, particularly in elderly or immunocompromised patients. The key symptom of bloody diarrhoea can occur in small epidemics through poor hygiene. In its most severe form, colitis may lead to perforation and the need for emergency colectomy, with an associated high mortality. Treatment involves resuscitation and antibiotic therapy with metronidazole or vancomycin. The fibrinous exudate is typical and differentiates the colitis from other inflammatory diseases; the laboratory recognition of the toxin is an early accurate diagnostic test.

Aerobic Gram-negative bacilli

These bacilli are normal inhabitants of the large bowel. *E. coli* and *Klebsiella* spp. are lactose fermenting; *Proteus* is non-lactose fermenting. Most organisms in this group act in synergy with *Bacteroides* to cause SSIs after bowel operations (in particular, appendicitis, diverticulitis and peritonitis). *E. coli* is a major cause of the HAI of urinary tract infection, although most aerobic Gram-negative bacilli (AGNB) may be involved, particularly in relation to urinary catheterisation. There is increasing concern about the development of ESBLs in many of this group

Figure 5.18 *Clostridium tetani* (drumstick spores).

of bacteria, which confer resistance to many antibiotics, particularly cephalosporins.

Pseudomonas spp. tend to colonise burns and tracheostomy wounds, as well as the urinary tract. Once *Pseudomonas* has colonised wards and intensive care units, it may be difficult to eradicate. Surveillance of cross-infection is important in outbreaks. Hospital strains become resistant to β -lactamase as resistance can be transferred by plasmids. Wound infections need antibiotic therapy only when there is progressive or spreading infection with systemic signs. The aminoglycosides are effective, but some cephalosporins and penicillin may not be. Many of the carbapenems (e.g. meropenem) are useful in severe infections, whereas the quinolones have been made ineffective through their overuse and the development of ESBLs.

Bacteroides

Bacteroides are non-spore-bearing, strict anaerobes that colonise the large bowel, vagina and oropharynx. *Bacteroides fragilis* is the principal organism that acts in synergy with AGNB to cause SSIs, including intra-abdominal abscesses, after colorectal or gynaecological surgery. They are sensitive to the imidazoles (e.g. metronidazole) and some cephalosporins (e.g. cefotaxime).

PRINCIPLES OF ANTIMICROBIAL TREATMENT

Antimicrobials may be used to prevent (see above under Prophylaxis) or treat established surgical infection (Summary box 5.16).

Summary box 5.16

Principles for the use of antibiotic therapy

- Antibiotics do not replace surgical drainage of infection
- Only spreading infection or signs of systemic infection justifies the use of antibiotics
- Whenever possible, the organism and sensitivity should be determined

The use of antibiotics for the treatment of established surgical infection ideally requires recognition and determination of the sensitivities of the causative organisms. Antibiotic therapy should not be held back if it is indicated, the choice being empirical and later modified depending on microbiological findings. However, once antibiotics have been administered, the clinical picture may become confused and, if a patient's condition does not rapidly improve, the opportunity to make a precise diagnosis may have been lost. It is unusual to have to treat SSIs with antibiotics, unless there is evidence of spreading infection, bacteraemia or systemic complications (SIRS and MODS). The appropriate treatment of localised SSIs is interventional radiological drainage of pus or open drainage and debridement.

Theodor Albrecht Edwin Klebs, 1834–1913, Professor of Bacteriology successively at Prague, Czechoslovakia; Zurich, Switzerland; and The Rush Medical College, Chicago, IL, USA.

There are two approaches to antibiotic treatment:

- 1 A **narrow-spectrum antibiotic** may be used to treat a known sensitive infection; for example, MRSA (which may be isolated from pus) is usually sensitive to vancomycin or teicoplanin, but not flucloxacillin.
- 2 **Combinations of broad-spectrum antibiotics** can be used when the organism is not known or when it is suspected that several bacteria, acting in synergy, may be responsible for the infection. For example, during and following emergency surgery requiring the opening of perforated or ischaemic bowel, any of the gut organisms may be responsible for subsequent peritoneal or bacteraemic infection. In this case, a triple-therapy combination of broad-spectrum penicillin (such as ampicillin or mezlocillin) with an aminoglycoside (such as gentamicin) and metronidazole, may be used pre- and postoperatively to support the patient's own body defences.

An alternative to the penicillins is a cephalosporin, e.g. cefuroxime. Other alternatives are piperacillin and tazobactam in combination or monotherapy using a carbapenem. The use of such broad-spectrum antibiotic strategies should be guided by specialist microbiological advice.

In surgical units in which resistant *Pseudomonas* or other Gram-negative species (such as *Klebsiella*) have become 'resident opportunists', it may be necessary to rotate anti-pseudomonal and anti-Gram-negative antibiotic therapy (Summary box 5.17).

Summary box 5.17

Treatment of commensals that have become opportunist pathogens

- They are likely to have multiple antibiotic resistance
- It may be necessary to rotate antibiotics

The use of these routines, subsequent wound infection and the alternation of combinations of chemotherapy should be monitored by the infection control team and local hospital protocols. In treating patients who have surgical infection with systemic signs (SIRS and MODS), a failure to respond to antibiotics may indicate that there has been a failure of infection source control. If response is poor after 3–4 days, there should be a re-evaluation with a review of charts and further investigations requested to exclude the development or persistence of infection such as a collection of pus.

New antibiotics should be used with caution and, wherever possible, sensitivities should first be obtained. There are certain general rules on which the choice of antibiotics may be based. For example, it is unusual for *Pseudomonas aeruginosa* to be found as a primary infecting organism unless the patient has had surgical or hospital treatment. Local antibiotic sensitivity patterns vary from centre to centre and from country to country, and the sensitivity patterns of common pathogens should be known to the hospital microbiologist who should be involved.

ANTIBIOTICS USED IN TREATMENT AND PROPHYLAXIS OF SURGICAL INFECTION

Antimicrobials may be produced by living organisms (antibiotics) or by synthetic methods. Some are bactericidal, e.g. penicillins and aminoglycosides, and others are bacteriostatic, e.g. tetracycline and erythromycin. In general, penicillins act upon the bacterial cell wall and are most effective against bacteria that are multiplying and synthesising new cell wall materials. The aminoglycosides act at the ribosomal level, preventing or distorting the production of proteins required to maintain the integrity of the enzymes in the bacterial cell. Hospital and Formulary guidelines should be consulted for doses and monitoring of antibiotic therapy.

Penicillin

Benzylpenicillin has proved most effective against Gram-positive pathogens, including most streptococci, the clostridia and some of the staphylococci that do not produce β -lactamase. It is still effective against *Actinomyces*, which is a rare cause of chronic wound infection, and may be used specifically to treat spreading streptococcal infections. Penicillin is valuable even if other antibiotics are required as part of multiple therapy for a mixed infection. All serious infections, e.g. gas gangrene, require high-dose intravenous benzylpenicillin.

Flucloxacillin

This is a β -lactamase-resistant penicillin and is therefore of use in treating most community-acquired staphylococcal infections, but it has poor activity against other pathogens.

Ampicillin and amoxicillin

These β -lactam penicillins can be taken orally or may be given parenterally. Both are effective against Enterobacteriaceae, *Enterococcus faecalis* and the majority of group D streptococci, but not species of *Klebsiella* or pseudomonads. Their use is now rare as there are more effective alternatives.

Mezlocillin and azlocillin

These are ureidopenicillins with good activity against species of *Enterobacter* and *Klebsiella*. Azlocillin is effective against *Pseudomonas*. Each has some activity against *Bacteroides* and enterococci, but all are susceptible to β -lactamases. Combined with an aminoglycoside, mezlocillin is a valuable treatment for severe mixed infections, particularly those caused by Gram-negative organisms in immunocompromised patients.

Clavulanic acid is available combined with amoxicillin (Augmentin) and can be taken orally. This anti- β -lactamase protects amoxicillin from inactivation by β -lactamase-producing bacteria. It is of value in treating infections caused by *Klebsiella* strains and β -lactamase-producing *E. coli* but is not active against *Pseudomonas* spp. It can be used for localised cellulitis or superficial staphylococcal infections and infected human and animal bites. It is available for oral or intravenous therapy.

Cephalosporins

There are several β -lactamase-susceptible cephalosporins that are of value in surgical practice: cefuroxime, cefotaxime and

ceftazidime are widely used. The first two are most effective in intra-abdominal skin and soft-tissue infections, being active against *Staphylococcus aureus* and most Enterobacteriaceae. As a group, the enterococci (*Streptococcus faecalis*) are not sensitive to the cephalosporins. Ceftazidime, although active against the Gram-negative organisms and *S. aureus*, is also effective against *P. aeruginosa*. These cephalosporins may be combined with an aminoglycoside, such as gentamicin, and an imidazole, such as metronidazole, if anaerobic cover is needed. Newer cephalosporins may be effective against organisms such as MRSA, but their spectra are usually limited.

Aminoglycosides

Gentamicin and tobramycin have similar activity and are effective against Gram-negative Enterobacteriaceae. Gentamicin is effective against many strains of *Pseudomonas*, although resistance has been recognised. All aminoglycosides are inactive against anaerobes and streptococci. Serum levels immediately before and 1 hour after intramuscular injection must be taken 48 hours after the start of therapy, and dosage should be modified to satisfy peak and trough levels. Ototoxicity and nephrotoxicity may follow sustained high toxic levels. These antibiotics have a marked post-antibiotic effect, and single, large doses are effective and may be safer. Use needs to be discussed with the microbiologist, and local policies should be observed.

Vancomycin

This glycopeptide is most active against Gram-positive bacteria and has proved to be effective against MRSA, although vancomycin resistance is increasingly being reported. However, it is ototoxic and nephrotoxic, so serum levels should be monitored. It is effective against *C. difficile* in cases of pseudomembranous colitis.

Imidazoles

Metronidazole is the most widely used member of the imidazole group and is active against all anaerobic bacteria. It is particularly safe and may be administered orally, rectally or intravenously. Infections caused by anaerobic cocci and strains of *Bacteroides* and clostridia can be treated, or prevented, by its use. Metronidazole is useful for the prophylaxis and treatment of anaerobic infections after abdominal, colorectal and pelvic surgery.

Carbapenems

Meropenem, ertapenem and imipenem are members of the carbapenems. They are stable to β -lactamase, have useful broad-spectrum anaerobic as well as Gram-positive activity and are effective for the treatment of resistant organisms, such as ESBL-resistant urinary tract infections or serious mixed-spectrum abdominal infections (peritonitis).

Quinolones

Quinolones, such as ciprofloxacin, were active against a wide spectrum of organisms. Their widespread use has been related to the development of resistant organisms, and their role in treating surgical infection is limited.

HUMAN IMMUNODEFICIENCY VIRUS, AIDS AND THE SURGEON

The type I human immunodeficiency virus (HIV) is one of the viruses of surgical importance as it can be transmitted by body fluids, particularly blood. It is a retrovirus that has become increasingly prevalent through sexual transmission, both homo- and heterosexual, in intravenous drug addiction, through infected blood in treating haemophiliacs, in particular, and in sub-Saharan Africans. The risk in surgery is probably mostly through 'needle stick' injury during operations.

After exposure, the virus binds to CD4 receptors with a subsequent loss of CD4⁺ cells, T-helper cells and other cells involved in cell-mediated immunity, antibody production and delayed hypersensitivity. Macrophages and gut-associated lymphoid tissue (GALT) are also affected. The risk of opportunistic infections (such as *Pneumocystis carinii* pneumonia, tuberculosis and cytomegalovirus) and neoplasms (such as Kaposi's sarcoma and lymphoma) is thereby increased.

In the early weeks after HIV infection, there may be a flu-like illness and, during the phase of seroconversion, patients present the greatest risk of HIV transmission. It is during these early phases that drug treatment, highly active anti-retroviral therapy (HAART), is most effective through the ability of these drugs to inhibit reverse transcriptase and protease synthesis, which are the principal mechanisms through which HIV can progress. Within two years, untreated HIV can progress to AIDS in 25–35 per cent of patients, which is considered to be fatal.

Involvement of surgeons with HIV patients (universal precautions)

Patients may present to surgeons for operative treatment if they have a surgical disease and they are known to be infected or 'at risk', or because they need surgical intervention related to their illness for vascular access or a biopsy when they are known to have HIV infection or AIDS. Universal precautions have been drawn up by the CDC in the United States and largely adopted by the NHS in the UK (in summary):

- when there is a risk of splashing, particularly with power tools, use of a full face mask ideally, or protective spectacles;
- use of fully waterproof, disposable gowns and drapes, particularly during seroconversion;
- boots to be worn, not clogs, to avoid injury from dropped sharps;
- double gloving needed (a larger size on the inside is more comfortable);
- allow only essential personnel in theatre;
- avoid unnecessary movement in theatre;
- respect is required for sharps, with passage in a kidney dish;
- a slow meticulous operative technique is needed with minimised bleeding.

After contamination

Needle-stick injuries are most common on the non-dominant index finger during operative surgery. Hollow needle injury carries the greatest risk of HIV transmission. The injured part should be washed under running water and the incident reported. Local policies dictate whether post-exposure HAART should be given. Occupational advice is required after high-risk

exposure together with the need for HIV testing and the option for continuation in an operative specialty.

Surgery in the tropics

LEARNING OBJECTIVES

To be aware of:

- The common surgical conditions that occur in the tropics

To appreciate:

- That many patients do not seek medical help until late in the course of the disease

To know:

- The emergency presentations of the various conditions as patients in developing countries do not seek treatment until they are very ill

To be able to:

- Diagnose and treat these conditions, particularly

as emergencies, because of the ease of global travel, visitors from the tropics would mostly present as an emergency in Western hospitals

To realise:

- That ideal management needs good teamwork between the surgeon, physician, radiologist, pathologist and microbiologist. In case of doubt in a difficult situation, there should be no hesitation in seeking help from London School of Hygiene and Tropical Medicine or Liverpool School of Tropical Medicine, the nation's foremost tropical medicine institutions.

INTRODUCTION

Most surgical conditions in the tropics are associated with parasitic infestations. With the ease of international travel, diseases that are common in the tropics and developing countries may be seen in the UK, especially presenting as emergencies.

This section deals with the conditions that a surgeon might occasionally encounter in a visitor to these shores. The life cycles of the parasites will not be dealt with. For academic interest readers are, however, advised to refer to the 24th edition of this book should they wish details of the parasitology. The principles of surgical treatment are dealt with in the appropriate sections although, for operative details, referral to a relevant textbook is advised.

AMOEBIASIS

Introduction

Amoebiasis is caused by *Entamoeba histolytica*. The disease is common in the Indian subcontinent, Africa and parts of Central and South America where almost half the population is infected. The majority remain asymptomatic carriers. The mode of infection is via the faeco-oral route, and the disease occurs as a result of substandard hygiene and sanitation; therefore the population from the poorer socioeconomic strata are more vulnerable. Amoebic liver abscess, the most common extraintestinal manifestation, occurs in less than 10 per cent of the infected population and, in endemic areas, is much more common than

pyogenic abscess. Patients who are immunocompromised and alcoholics are more susceptible to infection.

Pathogenesis

The organism enters the gut through food or water contaminated with the cyst. In the small bowel, the cysts hatch, and a large number of trophozoites are released and carried to the colon where flask-shaped ulcers form in the submucosa. The trophozoites multiply, ultimately forming cysts, which enter the portal circulation or are passed in the faeces as an infective form that infects other humans as a result of insanitary conditions.

Having entered the portal circulation, the trophozoites are filtered and trapped in the interlobular veins of the liver. They multiply in the portal triads causing focal infarction of hepatocytes and liquefactive necrosis as a result of proteolytic enzymes produced by the trophozoites. The areas of necrosis eventually coalesce to form the abscess cavity. The term 'amoebic hepatitis' is used to describe the microscopic picture in the absence of macroscopic abscess, a differentiation only in theory as the medical treatment is the same.

The right lobe is involved in 80 per cent of cases, the left in 10 per cent and the rest are multiple. Involvement of the right lobe of the liver is more common possibly because blood from the superior mesenteric vein runs on a straighter course through the portal vein into the larger lobe. The abscesses are most common high in the diaphragmatic surface of the right lobe. This may cause pulmonary symptoms and chest complications. The abscess cavity contains chocolate-coloured, odourless,

'anchovy sauce'-like fluid that is a mixture of necrotic liver tissue and blood. There may be secondary infection of the abscess. This causes the pus to smell. While pus in the abscess is sterile unless secondarily infected, trophozoites may be found in the abscess wall in a minority of cases. Untreated abscesses are likely to rupture.

Chronic infection of the large bowel may result in a granulomatous lesion along the large bowel, most commonly seen in the caecum, called an amoeboma (Summary box 6.1).

Summary box 6.1

Amoebiasis – pathology

- *Entamoeba histolytica* is the most common pathogenic amoeba in man
- The vast majority of carriers are asymptomatic
- Insanitary conditions and poor personal hygiene encourage transmission of the infection
- In the small intestine, the parasite hatches into trophozoites, which invade the submucosa producing flask-shaped ulcers
- In the portal circulation, the parasite causes liquefactive necrosis in the liver producing an abscess. This is the most common extraintestinal manifestation
- The majority of abscesses occur in the right lobe of the liver
- A mass in the course of the large bowel may indicate an amoeboma

Clinical features

The typical patient with amoebic liver abscess is a young adult male with a history of insidious onset of non-specific symptoms such as abdominal pain, anorexia, fever, night sweats, malaise, cough and weight loss; these symptoms gradually progress to more specific symptoms of pain in the right upper abdomen and right shoulder tip, hiccoughs and a non-productive cough. A past history of bloody diarrhoea or travel to an endemic area raises the index of suspicion.

Examination reveals a patient who is toxic and anaemic. The patient will have upper abdominal rigidity, tender hepatomegaly, tender and bulging intercostal spaces, overlying skin oedema, a pleural effusion and basal pneumonitis – the last feature is usually a late manifestation. Occasionally, a tinge of jaundice or ascites may be present. Rarely, the patient may present as an emergency due to the effects of rupture into the peritoneal, pleural or pericardial cavity.

Amoeboma

This is a chronic granuloma arising in the large bowel, most commonly seen in the caecum. It is prone to occur in long-standing amoebic infection that has been treated intermittently with drugs without completion of a full course, a situation that arises from indiscriminate self-medication, particularly in developing countries.

This can easily be mistaken for a carcinoma. An amoeboma should be suspected when a patient from an endemic area with generalised ill health and pyrexia has a mass in the right iliac fossa with a history of blood-stained mucoid diarrhoea. Such a patient is highly unlikely to have a carcinoma as altered bowel habit is not a feature of right-sided colonic carcinoma.

Investigations

The haematological and biochemical investigations reflect the presence of a chronic infective process: anaemia, leukocytosis, raised inflammatory markers – erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) – hypoalbuminaemia and deranged liver function tests, particularly elevated alkaline phosphatase.

Serological tests are more specific, with the majority of patients showing antibodies in serum. These can be detected by tests for complement fixation, indirect haemagglutination (IHA), indirect immunofluorescence and enzyme-linked immunosorbent assay (ELISA). They are extremely useful in detecting acute infection in non-endemic areas. IHA has a very high sensitivity rate in acute amoebic liver abscess in non-endemic regions and remains elevated for some time. The persistence of antibodies in a large majority of the population in endemic areas precludes its use there as a diagnostic investigation. In these cases, tests such as counter-immunoelectrophoresis are more useful for detecting acute infection.

An outpatient rigid sigmoidoscopy (using a disposable instrument) can be very useful, particularly if the patient complains of bloody mucoid diarrhoea. Most amoebic ulcers occur in the rectosigmoid and are therefore within reach of the sigmoidoscope; shallow skip lesions and 'flask-shaped' or 'collar-stud' undermined ulcers may be seen, and can be biopsied or scrapings can be taken along with mucus for immediate microscopic examination. The presence of trophozoites distinguishes the condition from ulcerative colitis.

Imaging techniques

On ultrasound, an abscess cavity in the liver is seen as a hypoechoic or anechoic lesion with ill-defined borders; internal echoes suggest necrotic material or debris (Figure 6.1). The investigation is very accurate and is used for aspiration, both diagnostic and therapeutic. Where there is doubt about the diagnosis, a computed tomography (CT) scan may be helpful (Figure 6.2).

Diagnostic aspiration is of limited value except for establishing the typical colour of the aspirate, which is sterile and odourless unless it is secondarily infected.

Figure 6.1 Ultrasound of the liver showing a large amoebic liver abscess with necrotic tissue in the right lobe.

Figure 6.2 Computed tomographic scan showing an amoebic liver abscess in the right lobe.

Figure 6.3 Computed tomographic scans showing multiple amoebic liver abscesses with extension into the chest.

A CT scan may show a raised right hemidiaphragm, a pleural effusion and evidence of pneumonitis (Figure 6.3).

An 'apple-core' deformity on barium enema would arouse suspicion of a carcinoma. A colonoscopy and biopsy are mandatory as the radiological and macroscopic appearance may be indistinguishable from a carcinoma. In doubtful cases, vigorous medical treatment is given, and the patient's colon is imaged again in 3–4 weeks, as these masses are known to regress completely on a full course of drug therapy. If symptoms persist even partially following full medical treatment in a patient who has recently returned from an endemic area, a colonic carcinoma must be excluded forthwith. This is because a dormant colonic carcinoma may become apparent as a result of infestation with amoebic dysentery causing 'traveller's diarrhoea'. However, it must be borne in mind that an amoeboma and carcinoma can coexist (Summary box 6.2).

Summary box 6.2

Diagnostic pointers for infection with *Entamoeba histolytica*

- Bloody mucoid diarrhoea in a patient from an endemic area or following a recent visit to such a country
- Upper abdominal pain, fever, cough, malaise
- In chronic cases, a mass in the right iliac fossa = amoeboma
- Sigmoidoscopy shows typical ulcers – biopsy and scraping may be diagnostic
- Serological tests are highly sensitive and specific outside endemic areas
- Ultrasound and CT scans are the imaging methods of choice

Treatment

Medical treatment is very effective and should be the first choice in the elective situation, with surgery being reserved for complications. Metronidazole and tinidazole are the effective drugs. After treatment with metronidazole and tinidazole, diloxanide furoate, which is not effective against hepatic infestation, is used for 10 days to destroy any intestinal amoebae.

Aspiration is carried out when imminent rupture of an abscess is expected. Aspiration also helps in the penetration of metronidazole, and so reduces the morbidity when carried out with drug treatment in a patient with a large abscess. If there is evidence of secondary infection, appropriate drug treatment is added. The threshold for aspirating an abscess in the left lobe is lower because of its predilection for rupturing into the pericardium.

Surgical treatment should be reserved for the complications of rupture into the pleural (usually the right side), peritoneal or pericardial cavities. Resuscitation, drainage and appropriate lavage with vigorous medical treatment are the key principles. In the large bowel, severe haemorrhage and toxic megacolon are rare complications. In these patients, the general principles of a surgical emergency apply. Resuscitation is followed by resection of bowel with exteriorisation. Then the patient is given vigorous supportive therapy. All such cases are managed in the intensive care unit as would any patient with toxic megacolon whatever the cause.

An amoeboma that has not regressed after full medical treatment should be managed with a colonic resection, particularly if cancer cannot be excluded (Summary box 6.3).

Summary box 6.3

Amoebiasis – treatment

- Medical treatment is very effective
- In large abscesses, repeated aspiration is combined with drug treatment
- Surgical treatment is reserved for complications such as rupture into the pleural, peritoneal or pericardial cavities
- Acute toxic megacolon and severe haemorrhage are intestinal complications that are treated with intensive supportive therapy followed by resection and exteriorisation
- When an amoeboma is suspected in a colonic mass, cancer should be excluded by appropriate imaging and biopsy

ASCARIS LUMBRICOIDES (ROUNDWORM)

Introduction

Ascaris lumbricoides, commonly called the roundworm, is the most common intestinal nematode to infest humans and affects a quarter of the world's population. The parasite causes pulmonary symptoms as a larva and intestinal symptoms as an adult worm.

Pathology and life cycle

The eggs can survive in a hostile environment for a long time. The hot and humid conditions in the tropics are ideally suited for the eggs to turn into embryos. The fertilised eggs are present in soil contaminated with infected faeces. Faeco-oral contamination causes human infection.

As the eggs are ingested, the released larvae travel to the liver via the portal system and then through the systemic circulation to reach the lung. The process of maturation takes up to 8 weeks. The developed larvae reach the alveoli, are coughed up, swallowed and continue their maturation in the small intestine. Sometimes, the young worm migrates from the tracheobronchial tree into the oesophagus, thus finding its way into the gastrointestinal tract, from where it can migrate to the common bile duct or pancreatic duct. The mature female, once in the small bowel, produces innumerable eggs that are fertilised and thereafter excreted in the stool to perpetuate the life cycle. Eggs in the biliary tract can form a nidus for a stone.

Clinical features

The larval stage in the lungs causes pulmonary symptoms – dry cough, chest pain, dyspnoea and fever – referred to as Loeffler's syndrome. The adult worm can grow up to 45 cm long. Its presence in the small intestine causes malnutrition, failure to thrive and abdominal pain. Worms that migrate into the common bile duct can produce ascending cholangitis and obstructive jaundice, while features of acute pancreatitis may be caused by a worm in the pancreatic duct.

Small intestinal obstruction can occur, particularly in children, due to a bolus of adult worms incarcerated in the terminal ileum. This is a surgical emergency. Rarely, perforation of the small bowel may occur from ischaemic pressure necrosis from the bolus of worms.

A high index of suspicion is necessary so as not to miss the diagnosis. If a person from a tropical developing country, or one who has recently returned after spending some time in an endemic area, presents with pulmonary, gastrointestinal, hepatobiliary and pancreatic symptoms, ascariasis infestation should be high on the list of possible diagnoses.

Investigations

Increase in the eosinophil count is common, in keeping with most parasitic infestations. Stool examination may show ova. Sputum or bronchoscopic washings may show Charcot–Leyden crystals or the larvae.

Chest x-ray may show fluffy exudates in Loeffler's syndrome. A barium meal and follow-through may show a bolus of worms in the ileum or lying freely within the small bowel (Figure 6.4). An ultrasound may show a worm in the common bile duct (Figure 6.5) or pancreatic duct. On magnetic resonance cholan-

giopancreatography (MRCP), an adult worm may be seen in the common bile duct in a patient presenting with features of obstructive jaundice (Figure 6.6) (Summary box 6.4).

Summary box 6.4

Ascariasis – pathogenesis

- It is the most common intestinal nematode affecting humans
- Typically found in a humid atmosphere and poor sanitary conditions; hence is seen in the tropics and developing countries
- Larvae cause pulmonary symptoms; adult worms cause gastrointestinal, biliary and pancreatic symptoms
- Distal ileal obstruction due to bolus of worms; ascending cholangitis and obstructive jaundice from infestation of the common bile duct
- Acute pancreatitis when a worm is lodged in the pancreatic duct
- Perforation of the small bowel is rare

Treatment

The pulmonary phase of the disease is usually self-limiting and requires symptomatic treatment only. For intestinal disease, patients should ideally be under the care of a physician for treatment with anthelmintic drugs. Certain drugs may cause rapid death of the adult worms and, if there are many worms in the terminal ileum, the treatment may actually precipitate acute intestinal obstruction from a bolus of dead worms. Children who present with features of intermittent or subacute obstruction should be given a trial of conservative management in the form of intravenous fluids, nasogastric suction and hypertonic saline enemas. The last of these helps to disentangle the bolus of worms and also increases intestinal motility.

Surgery is reserved for complications such as intestinal obstruction that has not resolved on a conservative regimen, and when perforation is suspected. At laparotomy, the bolus of worms in the terminal ileum is milked through the ileocaecal valve into the colon for natural passage in the stool. Postoperatively, hypertonic saline enemas may help in the extrusion of the worms. Strictures, gangrenous areas or perforations need resection and anastomosis. If the bowel wall is healthy, enterotomy and removal of the worms may be performed (Figure 6.7).

As a result of perforation due to roundworm, the parasites may be found lying free in the peritoneal cavity. The site of perforation may be brought out as an ileostomy because, in the presence of a large number of worms, closure or an anastomosis may be at risk of breakdown from the activity of the worms. Exteriorisation, although the ideal operation in severe sepsis, is unfortunately sometimes not done because of the reluctance on the part of the patient to accept such a procedure as good stoma care is not always available and follow up inadequate in developing countries. In such circumstances, resection of the diseased ileum, closure of the distal bowel and end-to-side ileotransverse anastomosis is a good alternative.

When a patient is operated upon as an emergency for a suspected complication of roundworm infestation, the actual diagnosis at operation may turn out to be acute appendicitis, typhoid perforation or tuberculous stricture, and the presence of roundworms is an incidental finding. Such a patient requires the appropriate surgery depending upon the pathology.

Figure 6.4 Barium meal and follow-through showing roundworms in the course of the small bowel with barium seen inside the worms in an 18-year-old patient who presented with bouts of colicky abdominal pain and bilious vomiting, which settled with conservative management (courtesy of Dr P Bhattacharya, Kolkata, India).

Figure 6.5 Ultrasound scan showing a roundworm in the common bile duct (CBD). The patient presented with obstructive jaundice and had asymptomatic gallstones. On endoscopic retrograde cholangiopancreatography (ERCP), part of the worm was seen outside the ampulla in the duodenum and was removed through the endoscope. Subsequent laparoscopic cholecystectomy was uneventful.

Figure 6.6 Magnetic resonance cholangiopancreatography (MRCP) showing a roundworm in the common bile duct (CBD). The worm could not be removed endoscopically. The patient underwent an open cholecystectomy and exploration of the CBD.

Figure 6.7 Roundworms removed at laparotomy in a 16-year-old patient who presented with acute intestinal obstruction (courtesy of the Pathology Museum, Calcutta Medical Research Institute, Kolkata, India).

Common bile duct or pancreatic duct obstruction from a roundworm can be treated by endoscopic removal, failing which open exploration of the common bile duct is necessary. Cholecystectomy is also carried out. A full course of anti-parasitic treatment must follow any surgical intervention (Summary box 6.5).

Summary box 6.5

Ascariasis – diagnosis and management

- Barium meal and follow-through will show worms scattered in the small bowel
- Ultrasound may show worms in the common bile duct and pancreatic duct
- Conservative management with anthelmintics is the first line of treatment even in obstruction
- Surgery is a last resort – various options are available

ASIATIC CHOLANGIOHEPATITIS

Introduction

This disease, also called oriental cholangiohepatitis, is caused by infestation of the hepatobiliary system by *Clonorchis sinensis*. It has a high incidence in the tropical regions of South East Asia, particularly among those living in the major sea ports and river estuaries. The organism, which is a type of liver fluke, resides in snails and fish that act as intermediate hosts. Ingestion of infected fish and snails when eaten raw or partly cooked causes the infection in humans and other fish-eating mammals, which are the definitive hosts.

Pathology

In humans, the parasite matures into the adult worm in the intrahepatic biliary radicles where they may reside for many years. The intrahepatic bile ducts are dilated with epithelial hyperplasia and periductal fibrosis. These changes may lead to dysplasia causing cholangiocarcinoma – the most serious complication of this parasitic infestation.

The eggs or dead worms may form a nidus for stone formation in the gall bladder or common bile duct, which becomes thickened and much dilated in the late stages. Intrahepatic bile duct stones are also caused by the parasite producing mucin-rich bile. The dilated intrahepatic bile ducts may lead to cholangitis, liver abscess and hepatitis.

Diagnosis

The disease may remain dormant for many years. Clinical features are non-specific, such as fever, malaise, anorexia and upper abdominal discomfort. The complete clinical picture can consist of fever with rigors due to ascending cholangitis, obstructive jaundice due to stones, biliary colic and pruritis. Acute pancreatitis may occur because of obstruction of the pancreatic duct by an adult worm. If any person or an emigrant to the West from an endemic area complains of symptoms of biliary tract disease, *Clonorchis* infestation should be considered in the differential diagnosis.

In advanced cases, liver function tests are abnormal. Confirmation of the condition is by examination of stool or duodenal aspirate, which may show the eggs or adult worms. Ultrasound scan findings can be characteristic, showing the uniform dilatation of small peripheral intrahepatic bile ducts with only minimal dilatation of the common hepatic and common bile ducts, although the latter are much more dilated when the obstruction is caused by stones. The thickened duct walls show increased echogenicity and non-shadowing echogenic foci in the bile ducts representing the worms or eggs. Endoscopic retrograde cholangiopancreatography (ERCP) will confirm these findings (Summary box 6.6).

Treatment

Praziquantel and albendazole are the drugs of choice. However, the surgeon faces a challenge when there are stones not only in the gall bladder but also in the common bile duct. Cholecystectomy with exploration of the common bile duct is performed when indicated. Repeated washouts are necessary during the exploration, as the common bile duct is dilated and

Summary box 6.6

Asiatic cholangiohepatitis – pathogenesis and diagnosis

- Occurs in the Far Eastern tropical zones
- Causative parasite is *Clonorchis sinensis*
- Produces bile duct hyperplasia, intrahepatic duct dilatation and stones
- Increases the risk of cholangiocarcinoma
- May remain dormant for many years
- When active, there are biliary tract symptoms in a generally unwell patient
- Stool examination for eggs or worms is diagnostic
- Ultrasound scan of hepatobiliary system and ERCP are also diagnostic

contains stones, biliary debris, sludge and mud. This should be followed by choledochoduodenostomy. As this is a disease with a prolonged and relapsing course, some surgeons prefer to do a choledochojejunostomy to a Roux loop. The Roux loop is brought up to the abdominal wall, referred to as 'an access loop', which allows the interventional radiologist to deal with any future stones.

As a public health measure, people who have emigrated to the West from an endemic area should be offered screening for *Clonorchis* infestation in the form of ultrasound of the hepatobiliary system. This condition can be diagnosed and treated and even cured when it is in its subclinical form. Most importantly, the risk of developing the dreadful disease of cholangiocarcinoma is eliminated (Summary box 6.7).

Summary box 6.7

Asiatic cholangiohepatitis – treatment

- Medical treatment can be curative in the early stages
- Surgical treatment is cholecystectomy, exploration of the common bile duct and some form of biliary–enteric bypass
- Prevention – consider offering hepatobiliary ultrasound as a screening procedure to recently arrived migrants to the West from endemic areas

FILARIASIS

Introduction

Filariasis is mainly caused by the parasite *Wuchereria bancrofti* carried by the mosquito. A variant of the parasite called *Brugia malayi* and *B. timori* is responsible for causing the disease in about 10 per cent of sufferers. The condition affects more than 90 million people worldwide, two-thirds of whom live in India, China and Indonesia. According to the World Health Organization (WHO), filariasis is the second most common cause, after leprosy, of long-term disability.

Once bitten by the mosquito, the matured eggs enter the human circulation to hatch and grow into adult worms; the process of maturation takes about one year. The adult worms mainly colonise the lymphatic system.

Figure 6.8 Left lower limb filariasis – elephantiasis (courtesy of Professor Ahmed Hassan Fahal, Khartoum, Sudan).

Diagnosis

It is mainly males who are affected because females, in general, cover a greater part of their bodies, thus making them less prone to mosquito bites. In the acute presentation, there are episodic attacks of fever with lymphadenitis and lymphangitis.

Occasionally, adult worms may be felt subcutaneously. Chronic manifestations appear after repeated acute attacks over several years. The adult worms cause lymphatic obstruction resulting in massive lower limb oedema. Obstruction to the cutaneous lymphatics causes skin thickening, not unlike the 'peau d'orange' appearance in breast cancer, thus exacerbating the limb swelling. Secondary streptococcal infection is common. Recurrent attacks of lymphangitis cause fibrosis of the lymph channels, resulting in a grossly swollen limb with thickened skin producing the condition of elephantiasis (Figure 6.8). Bilateral lower limb filariasis is often associated with scrotal and penile elephantiasis. Early on, there may be a hydrocoele underlying scrotal filariasis (Figure 6.9).

Chyluria and chylous ascites may occur. A mild form of the disease can affect the respiratory tract, causing dry cough, and is referred to as tropical pulmonary eosinophilia. The condition of filariasis is clinically very obvious, and thus investigations in the full-blown case are superfluous. Eosinophilia is common, and a nocturnal peripheral blood smear may show the immature forms or microfilariae. The parasite may also be seen in chylous urine, ascites and hydrocoele fluid.

Treatment

Medical treatment with diethylcarbamazine is very effective in the early stages before the gross deformities of elephantiasis have developed. In the early stages of limb swelling, intermit-

Figure 6.9 Filariasis of the scrotum (courtesy of Professor Ahmed Hassan Fahal, Khartoum, Sudan).

tent pneumatic compression helps, but the treatment has to be repeated over a prolonged period.

A hydrocoele is treated by the usual operation of excision and eversion of the sac with, if necessary, excision of redundant skin. Operations for reducing the size of the limb are hardly ever done these days because the procedures are rarely successful (Summary box 6.8).

Summary box 6.8

Filariasis

- Caused by *Wuchereria bancrofti* that is carried by the mosquito
- Lymphatics are mainly affected, resulting in gross limb swelling
- Eosinophilia; immature worms seen in a nocturnal peripheral blood smear
- Gross forms of the disease cause a great deal of disability and misery
- Early cases are very amenable to medical treatment
- Intermittent pneumatic compression gives some relief
- The value of various surgical procedures is largely unproven

HYDATID DISEASE

Introduction and pathology

Commonly called dog tape worm, hydatid disease is caused by *Echinococcus granulosus*. While it is common in the tropics, in the UK, the occasional patient may come from a rural sheep-farming community.

The dog is the definitive host and, as a pet, is the most common source of infection transmitted to the intermediate hosts – humans, sheep and cattle. In the dog, the adult worm reaches the small intestine, and the eggs are passed in the faeces. These eggs are highly resistant to extremes of temperature and may survive for long periods. In the dog's intestine, the cyst

Otto Eduard Heinrich Wucherer, 1820–1873, a German physician who practised in Brazil, South America.

Peau d'orange is French for 'orange skin'.

Joseph Bancroft, 1836–1894, an English physician who worked in Australia.

Figure 6.10 Computed tomographic scan showing a hydatid cyst of the pancreas. A differential diagnosis of hydatid cyst or a tumour was considered. At exploration, the patient was found to have a hydatid cyst, which was excised followed by a 30-month treatment with albendazole. The patient remains free of disease.

wall is digested, allowing the protoscolices to develop into adult worms. Close contact with the infected dog causes contamination by the oral route, with the ovum thus gaining entry into the human gastrointestinal tract.

The cyst is characterised by three layers, an outer **pericyst** derived from compressed host organ tissues, an intermediate hyaline **ectocyst** which is non-infective and an inner **endocyst** that is the germinal membrane and contains viable parasites which can separate forming daughter cysts. A variant of the disease occurs in colder climates caused by *Echinococcus multilocularis*, in which the cyst spreads from the outset by actual invasion rather than expansion.

Classification

In 2003, the WHO Informal Working Group on Echinococcosis (WHO-IWGE) proposed a standardised ultrasound classification based on the status of activity of the cyst. This is universally accepted, particularly because it helps to decide on the appropriate management. Three groups have been recognised:

- Group 1: Active group – cysts larger than 2 cm and often fertile
- Group 2: Transition group – cysts starting to degenerate and entering a transitional stage because of host resistance or treatment, but may contain viable protoscolices
- Group 3: Inactive group – degenerated, partially or totally calcified cysts; unlikely to contain viable protoscolices.

Clinical features

As the parasite can colonise virtually every organ in the body, the condition can be protean in its presentation. When a sheep farmer, who is otherwise healthy, complains of a gradually enlarging painful mass in the right upper quadrant with the physical findings of a liver swelling, a hydatid liver cyst should be considered. The liver is the organ most often affected. The lung is the next most common. The parasite can affect any organ (Figures 6.10 and 6.11) or several organs in the same patient (Figure 6.12).

The disease may be asymptomatic and discovered coinciden-

Figure 6.11 Anteroposterior (a) and lateral (b) views of computed tomographic scans showing a large hydatid cyst of the right adrenal gland. The patient presented with a mass in the right loin and underwent an adrenalectomy (courtesy of Dr P Bhattacharaya, Kolkata, India).

Figure 6.12 Computed tomographic scan showing disseminated hydatid cysts of the abdomen. The patient was started on albendazole and lost to follow up (courtesy of Dr P Bhattacharaya, Kolkata, India).

Figure 6.13 Magnetic resonance cholangiopancreatography (MRCP) showing a large hepatic hydatid cyst with daughter cysts communicating with the common bile duct causing obstruction and dilatation of the entire biliary tree (courtesy of Dr B Agarwal, New Delhi, India).

tally at post-mortem or when an ultrasound or CT scan is done for some other condition. Symptomatic disease presents with a swelling causing pressure effects. Thus, a hepatic lesion causes dull pain from stretching of the liver capsule, and a pulmonary lesion, if large enough, causes dyspnoea. Daughter cysts may communicate with the biliary tree causing obstructive jaundice and all the usual clinical features associated with it in addition to symptoms attributable to a parasitic infestation (Figure 6.13). Features of raised intracranial pressure or unexplained headaches in a patient from a sheep-rearing community should raise the suspicion of a cerebral hydatid cyst.

The patient may present as an emergency with severe abdominal pain following minor trauma when the CT scan may be diagnostic (Figure 6.14). Rarely, a patient may present as an

Figure 6.14 Computed tomographic (CT) scan of the upper abdomen showing a hypodense lesion of the left lobe of the liver; the periphery of the lesion shows a double edge. This is the lamellar membrane of the hydatid cyst that separated after trivial injury. The patient was a 14-year-old girl who developed a rash and pain in the upper abdomen after dancing. The rash settled down after a course of antihistamines. The CT scan was done 2 weeks later for persisting upper abdominal pain.

emergency with features of anaphylactic shock without any obvious cause. Such a patient may subsequently cough up white material that contains scolices that have travelled into the tracheobronchial tree from rupture of a hepatic hydatid on the diaphragmatic surface of the liver.

Diagnosis

There should be a high index of suspicion. Investigations show a raised eosinophil count; serological tests such as ELISA and immunoelectrophoresis point towards the diagnosis. Ultrasound and CT scan are the investigations of choice. The CT scan shows a smooth space-occupying lesion with several septa. An ultrasound of the biliary tract may show abnormality in the gall bladder and bile ducts. Hydatid infestation of the biliary system should then be suspected. Ultimately, the diagnosis is made by a combination of good history and clinical examination supplemented by serology and radiological imaging techniques (Summary box 6.9).

Summary box 6.9

Hydatid disease – diagnosis

- In the UK, the usual sufferer is a sheep farmer
- While any organ may be involved, the liver is by far the most commonly affected
- Elective clinical presentation is usually in the form of a painful lump arising from the liver
- Anaphylactic shock due to rupture of the hydatid cyst is the emergency presentation
- CT scan is the best imaging modality – the diagnostic feature is a space-occupying lesion with a smooth outline with septa

Treatment

Here, the treatment of hepatic hydatid is outlined as the liver is most commonly affected, but the same general principles apply whichever organ is involved.

These patients should be treated in a tertiary unit where good teamwork between an expert hepatobiliary surgeon, an experienced physician and an interventional radiologist is available. Surgical treatment by minimal access therapy is best summarised by the mnemonic PAIR (puncture, aspiration, injection and reaspiration). This is done after adequate drug treatment with albendazole, although praziquantel has also been used, both these drugs being available only on a 'named patient' basis.

Whether the patient is treated only medically or in combination with surgery will depend upon the clinical group (which gives an idea as to its activity), the number of cysts and their anatomical position. Radical total or partial pericystectomy with omentoplasty or hepatic segmentectomy (especially if the lesion is in a peripheral part of the liver) are some of the surgical options. During the operation, scolical agents are used, such as hypertonic saline (15–20 per cent), ethanol (75–95 per cent) or 1 per cent povidone iodine, although some use a 10 per cent solution. This may cause sclerosing cholangitis if biliary radicles are in communication with the cyst wall. A laparoscopic approach to these procedures is being tried.

Obviously, cysts in other organs need to be treated in accordance with the actual anatomical site along with the general principles described. An asymptomatic cyst which is inactive (group 3) may just be observed (Summary box 6.10).

Summary box 6.10

Hydatid cyst of the liver – treatment

- Ideally managed in a tertiary unit by a multidisciplinary team of hepatobiliary surgeon, physician and interventional radiologist
- Leave asymptomatic and inactive cysts alone – monitor size by ultrasound
- Active cysts should first be treated by a full course of albendazole
- Several procedures are available – PAIR, pericystectomy with omentoplasty and hepatic segmentectomy; it is important to choose the most appropriate option for the particular patient and organ involved
- Increasingly, a laparoscopic approach is being tried

Pulmonary hydatid disease

The lung is the second most common organ affected after the liver. The size of the cyst can vary from being very small to a considerable size. The right lung and lower lobes are slightly more often involved. The cyst is usually single, although multiple cysts do occur and concomitant hydatid cysts in other organs like the liver are not unknown. The condition may be silent and found incidentally. Symptomatic patients present with cough, expectoration, fever, chest pain and sometimes haemoptysis. Silent cysts may present as an emergency due to rupture or an allergic reaction.

Uncomplicated cysts present as rounded or oval lesions on chest x-ray. Erosion of the bronchioles results in air being introduced between the pericyst and the laminated membrane and

gives a fine radiolucent crescent, the 'meniscus or crescent sign' (Figure 6.15). This is often regarded as a sign of impending rupture. When the cyst ruptures, the crumpled collapsed endocyst floats in the residual fluid giving rise to the 'water-lily' sign on CT scan (Figure 6.16). Rupture into the pleural cavity results in pleural effusion. CT scan defines the pathology in greater detail.

The mainstay of treatment of hydatidosis of the lung is surgery. Medical treatment is less successful and considered when surgery is not possible because of poor general condition or diffuse

Figure 6.15 Chest x-ray: (a) a smooth rounded cystic lesion in the right lower lobe; (b) 'meniscus or crescent' sign (courtesy of Professor Saibal Gupta, Professor of Cardiovascular Surgery, Kolkata, India and Dr Rupak Bhattacharya, Kolkata, India).

Figure 6.16 Computed tomographic scan showing the 'water-lily' sign. A young mountaineer, while on a high altitude trip, complained of sudden shortness of breath, cough, copious expectoration consisting of clear fluid and flaky material. At first thought to be due to pulmonary oedema, it turned out to be a ruptured hydatid cyst, which was successfully treated by surgery (courtesy of Professor Saibal Gupta, Professor of Cardiovascular Surgery, Kolkata, India and Dr Rupak Bhattacharya, Kolkata, India).

disease affecting both lungs, or recurrent or ruptured cysts. The principle of surgery is to preserve as much of viable lung tissue as possible. The exact procedure can vary: cystotomy, capittonage (suturing together the walls), pericystectomy, segmentectomy or occasionally pneumonectomy (Summary box 6.11).

Summary box 6.11

Pulmonary hydatid disease

- Second most common organ involved
- Size of the cyst has a wide variation
- May present as an incidental finding
- Clinical presentation may be elective or emergency due to rupture
- Plain x-ray shows 'meniscus or crescent' sign; CT shows 'water-lily' sign
- Ideal treatment is surgical – various choices are available

LEPROSY

Introduction

Leprosy, also called Hansen's disease, is a chronic infectious disease caused by the acid-fast bacillus, *Mycobacterium leprae*, that is widely prevalent in the tropics. Globally, India, Brazil, Nepal, Mozambique, Angola and Myanmar (Burma) account for 91 per cent of all the cases; India alone accounts for 78 per cent of the world's disease. Patients suffer not only from the primary

effects of the disease but also from social discrimination, sadly compounded by the inappropriate term 'leper' for one afflicted with this disease.

Only close contact over a long time of several years causes the disease to spread. Ignorance of this fact on the part of the general public results in ostracism from social stigma. History records that in the distant past sufferers were made to wear cow bells so that other people could avoid them. The use of the term 'leper', still used metaphorically to denote an outcast, does not help to break down the social barriers that continue to exist against the sufferer.

Pathology

The bacillus inhabits the colder parts of the body – hence found in the nasal mucosa and skin in the region of the ears thus involving the facial nerve as it exits from the stylomastoid foramen. The disease is transmitted from the nasal secretions of a patient, the infection being contracted in childhood or early adolescence. After an incubation period of several years, the disease presents with skin, upper respiratory or neurological manifestations. The bacillus is acid fast but weakly so compared with *Mycobacterium tuberculosis*.

The disease is broadly classified into two groups – lepromatous and tuberculoid. In lepromatous leprosy, there is widespread dissemination of abundant bacilli in the tissues with macrophages and a few lymphocytes. This is a reflection of the poor immune response, resulting in depleted host resistance from the patient. In tuberculoid leprosy, on the other hand, the patient shows a strong immune response with scant bacilli in the tissues, epithelioid granulomas, numerous lymphocytes and giant cells. The tissue damage is inversely proportional to the host's immune response. There are various grades of the disease between the two main spectra (Summary box 6.12).

Summary box 6.12

Mycobacterium leprae – pathology

- Leprosy is a chronic curable infection caused by *Mycobacterium leprae*
- It occurs mainly in tropical regions and developing countries
- The majority of cases are located in the Indian subcontinent
- Transmission is through nasal secretions, the bacillus inhabiting the colder parts of the body
- It is attributed to poor hygiene and insanitary conditions
- The incubation period is several years
- The initial infection occurs in childhood
- Lepromatous leprosy denotes a poor host immune reaction
- Tuberculoid leprosy occurs when host resistance is stronger than virulence of the organism

Clinical features and diagnosis

The disease is slowly progressive and affects the skin, upper respiratory tract and peripheral nerves. In tuberculoid leprosy, the damage to tissues occurs early and is localised to one part of the body with limited deformity of that organ. Neural involvement

Robert Greenhill Cochrane, 1899–1985, a medical missionary who became an international authority on leprosy; he devoted his time to leprosy patients in South East Asia, particularly India.

Figure 6.17 Lateral view of the face showing collapse of the nasal bridge due to destruction of nasal cartilage by leprosy.

is characterised by thickening of the nerves, which are tender. There may be asymmetrical well-defined anaesthetic hypopigmented or erythematous macules with elevated edges and a dry and rough surface – lesions called leprids. In lepromatous leprosy, the disease is symmetrical and extensive. Cutaneous involvement occurs in the form of several pale macules that form plaques and nodules called lepromas. The deformities produced are divided into primary, which are caused by leprosy or its reactions, and secondary, resulting from effects such as anaesthesia of the hands and feet.

Nodular lesions on the face in the acute phase of the lepromatous variety are known as 'leonine facies' (looking like a lion).

Figure 6.18 Frontal view of the face showing eye changes in leprosy – paralysis of orbicularis oculi and loss of eyebrows.

Later, there is wrinkling of the skin giving an aged appearance to a young individual. There is loss of the eyebrows and destruction of the lateral cartilages and septum of the nose with collapse of the nasal bridge and lifting of the tip of the nose (Figure 6.17). There may be paralysis of the branches of the facial nerve in the bony canal or of the zygomatic branch. Blindness may be attributed to exposure keratitis or iridocyclitis. Paralysis of the orbicularis oculi causes incomplete closure of the eye, epiphora and conjunctivitis (Figure 6.18). The hands are typically clawed (Figure 6.19) because of involvement of the ulnar nerve at the elbow and the median nerve at the wrist. Anaesthesia of the hands makes these patients vulnerable to frequent burns and injuries. Similarly, clawing of the toes (Figure 6.20) occurs as a result of involvement of the posterior tibial nerve. When the lateral popliteal nerve is affected, it leads to foot drop, and the nerve can be felt to be thickened behind the upper end of the fibula. Anaesthesia of the feet predisposes to trophic ulceration

Figure 6.19 (a and b) Typical bilateral claw hand from leprosy due to involvement of the ulnar and median nerves.

Figure 6.20 Claw toes from involvement of the posterior tibial nerve by leprosy; also note autoamputation of toes of the right foot.

(Figure 6.21), chronic infection, contraction and autoamputation. Involvement of the testes causes atrophy, which in turn results in gynaecomastia (Figure 6.22). Confirmation of the diagnosis is obtained by a skin smear or skin biopsy, which shows the classical histological and microbiological features (Summary box 6.13).

Summary box 6.13

Leprosy – diagnosis

- Typical clinical features and awareness of the disease should help to make a diagnosis
- The face has an aged look about it with collapse of the nasal bridge and eye changes
- Thickened peripheral nerves, patches of anaesthetic skin, claw hands, foot drop and trophic ulcers are characteristic
- Microbiological examination of the acid-fast bacillus and typical histology on skin biopsy are confirmatory

Treatment

A herbal derivative from the seeds of *Hydrocarpus wightiana* called chalmogra oil was the mainstay of treatment with some success until the advent of dapsone (diamino-diphenyl sulphone). Dapsone, one of the principal drugs, was a derivative of prontosil red. This is used according to the WHO guidelines along with rifampicin and clofazimine. During treatment, the patient may develop acute manifestations. These are controlled with steroids. Multiple drug therapy for 12 months is the key to treatment. A team approach between an infectious diseases specialist, plastic surgeon, ophthalmologist, hand and orthopaedic surgeon is important.

Surgical treatment is indicated in advanced stages of the disease for functional disability of limbs, cosmetic disfigurement of the face and visual problems. These entail major reconstructive surgery, the domain of the plastic surgeon. Deformities of the hands and feet require various forms of tendon transfer, which need to be carried out by specialist hand or orthopaedic surgeons.

The general surgeon may be called upon to treat a patient when the deformity is so advanced that it requires amputation, or when abscesses need to be drained as an emergency.

Figure 6.21 Bilateral trophic ulceration of the feet due to anaesthesia of the soles resulting from leprosy; also note claw toes on the left foot.

All surgical procedures obviously need to be done under anti-leprosy drug treatment. This is best achieved by a team approach. Educating the patients about the dreadful sequelae of the disease so that they seek medical help early is important. It is also necessary to educate the general public that patients suffering from the disease should not be made social outcasts (Summary box 6.14).

Summary box 6.14

Leprosy – treatment

- Multiple drug therapy for a year
- Team approach
- Surgical reconstruction requires the expertise of a hand surgeon, orthopaedic surgeon and plastic surgeon
- Education of the patient and general public should be the keystone in prevention

Gerhard Domagk, 1895–1964, German physician, Lecturer in Pathologic Anatomy, University of Munster, Germany, discovered prontosil in 1935, for which he was awarded the Nobel Prize for Physiology or Medicine in 1939.

Paul Wilson Brand, 1914–2003, born to missionary parents in Southern India, qualified London 1943 CBE, FRCS. He himself was a dedicated missionary who was 'an extraordinary gifted orthopaedic surgeon who straightened crooked hands and unravelled the riddle of leprosy.' As a pioneer in tendon transfer techniques, he established and practised initially in New Life Center, Vellore, South India and Schieffelin Leprosy Research Centre, Karigiri, South India. Initially he trained as a carpenter and builder and maintained that his training as a carpenter helped him in his expertise in tendon transplantation. He later moved to Louisiana State University, Baton Rouge, LA, where he continued his work and finally to Seattle as Emeritus Professor of Orthopaedics in the University of Washington, Seattle, USA.

Margaret Brand, alongside her husband, Paul Brand, also contributed immensely to leprosy patients by concentrating on research to prevent blindness in leprosy. She became known as 'the woman who first helped lepers to see'.

Frank Tovey OBE (b.1921), another English surgeon. At about the same time (1951–1967) in Southern India in the state of Mysore, as a general surgeon, also performed extensive tendon transfers, facial and other reconstructive surgery on leprosy patients; in this he was helped by his wife, Winifred, who organised the physiotherapy and rehabilitation of the patients and established village diagnostic and treatment centres.

MYCETOMA

(This section has been contributed by Professor Ahmed Hassan Fahal MBBS, FRCS, FRCSI, MD, MS, FRCP(Lond) Professor of Surgery, University of Khartoum, Khartoum, Sudan)

Introduction

Mycetoma is a chronic specific, granulomatous, progressive, destructive inflammatory disease, which involves subcutaneous tissues spreading to the skin and deeper structures. The causative organism may be true fungi when the condition is called eumycetoma; when caused by bacteria it is called actinomycetoma. The pathognomonic feature is the triad of painless subcutaneous mass, multiple sinuses and seropurulent discharge. It causes tissue destruction, deformity, disability and death in extreme cases.

Epidemiology and pathogenesis

The condition predominantly occurs in the 'mycetoma belt' that lies between the latitudes 15° south and 30° north comprising the countries of Sudan, Somalia, Senegal, India, Yemen, Mexico, Venezuela, Columbia, Argentina and a few others. The route of infection is inoculation of the organism that is resident in the soil through a traumatised area. Although in the vast majority there is no history of trauma, the portal of entry is always an area of minor unrecognised trauma in a bare-footed individual walking in a terrain full of thorns. Hence the foot is the most common site affected. Mycetoma is not contagious.

Once the granuloma forms it increases in size, the overlying skin becomes stretched, smooth, shiny, and attached to the lesion. Areas of hypo or hyperpigmentation sometimes develop. Eventually it invades the deeper structures. This is usually gradual and delayed in eumycetoma. In actinomycetoma, invasion to deeper tissues occurs earlier and is more extensive. The tendons and the nerves are spared until late in the disease. This may explain the rarity of neurological and trophic changes even

in patients with long-standing disease. Trophic changes are rare because the blood supply is adequate (Summary box 6.15).

Summary box 6.15

Mycetoma – pathogenesis

- Mostly occurs in the 'mycetoma belt'
- There are two types – eumycetoma and actinomycetoma
- Caused by fungi or bacteria entering through a site of trauma which may not be apparent; hence foot most commonly affected
- Produces a chronic, specific, granulomatous, progressive, destructive inflammatory lesion
- Results in tissue destruction, deformity, disability and sometimes death

Clinical presentation

As mycetoma is painless, presentation is late in the majority. It presents as a slowly progressive, painless, subcutaneous swelling commonly at the site of presumed trauma. The swelling is variable in its physical characteristics: firm and rounded, soft and lobulated, rarely cystic and is often mobile. Multiple secondary nodules may evolve; they may suppurate and drain through multiple sinus tracts. The sinuses may close transiently after discharge during the active phase of the disease. Fresh adjacent sinuses may open while some of the old ones may heal completely. They coalesce and form abscesses, the discharge being serous, serosanguinous or purulent. During the active phase of the disease the sinuses discharge grains, the colour of which can be black, yellow, white or red depending upon the organism. Pain may supervene when there is secondary bacterial infection.

In some patients there may be areas of local hyperhidrosis over the lesion. This may be due to sympathetic overactivity or increased local temperature due to raised arterial blood flow caused by the chronic inflammation. In the majority of patients, the regional lymph nodes are small and shotty. Lymphadenopathy is common. This may be due to secondary bacterial infection, lymphatic spread of mycetoma or a local immune response to the disease.

The common sites affected are those that come into contact with soil during daily activities: foot in 70 per cent (Figure 6.23) and hand in 12 per cent (Figure 6.24). In endemic areas, the

Figure 6.23 Mycetoma of foot.

Figure 6.24 Mycetoma of hand.

Figure 6.25 Mycetoma of knee.

Figure 6.26 Actinomycetoma of head and neck.

Figure 6.27 Extensive satellite inguinal actinomycetoma from primary foot lesion involving anterior abdominal wall and perineum.

knee (Figure 6.25), arm, leg, head and neck (Figure 6.26), thigh and perineum (Figure 6.27) can be involved. Rare sites are chest, abdominal wall, facial bones, mandible, testes, paranasal sinuses and eye.

The condition remains localised; constitutional disturbances are a sign of secondary bacterial infection. Cachexia and anaemia from malnutrition and sepsis may be seen in late cases. It can be fatal, especially in cases of cranial mycetoma.

Spread

Local spread occurs predominantly along tissue planes. The organism multiplies forming colonies which spread along the fascial planes to skin and underlying structures. Lymphatic spread occurs to the regional lymph nodes. During the active phase of the disease, these lymphatic satellites may suppurate and discharge. Lymphatic spread is more common in actinomycetoma and its incidence is augmented by repeated inadequate surgical excision; lymphadenopathy may also be due to secondary bacterial infection. Spread by blood stream can occur.

The apparent clinical features of mycetoma are not always a reliable indicator of the extent and spread of the disease. Some small lesions with few sinuses may have many deep connecting tracts, through which the disease can spread quite extensively; therefore, surgery in mycetoma under local anaesthesia is contraindicated.

Differential diagnosis

Mycetoma should be distinguished from Kaposi's sarcoma, malignant melanoma, fibroma and foreign body (thorn) granuloma. In an x-ray the presence of bone destruction in the absence of sinuses is suggestive of tuberculosis. The radiological features of advanced mycetoma are similar to primary osteogenic sarcoma. Primary osseous mycetoma is to be differentiated from chronic osteomyelitis, osteoclastoma, bone cysts and syphilitic osteitis.

Moritz Kaposi, 1837–1902, Hungarian born, Professor of Dermatology, University of Vienna, Austria. Was born to a Jewish family, originally his surname was Kohn. When he converted to Catholicism in 1871, he changed his surname to Kaposi. He described the sarcoma in 1872. The viral cause was discovered in 1994.

Figure 6.28 Plain x-ray of knee showing multiple large cavities involving the lower femur, upper tibia and fibula with well-defined margins and periosteal reaction typical of eumycetoma.

In endemic areas the dictum should be 'any subcutaneous swelling must be considered a mycetoma until proven otherwise'.

Diagnosis

Several imaging techniques are available to confirm the diagnosis: plain x-ray, ultrasound, CT scan and magnetic resonance imaging (MRI).

Plain x-ray

In the early stages, soft tissue shadow which may be multiple may be seen with calcification and obliteration of the fascial planes. As the disease progresses, the cortex may be compressed from outside by the granuloma leading to bone scalloping. Periosteal reaction with new bone spicules may create a sun-ray appearance and Codman's triangle, not unlike in osteogenic sarcoma (Figure 6.28). Late in the disease, there may be multiple punched-out cavities throughout the bone.

Ultrasound

Ultrasound can differentiate between eumycetoma and actinomycetoma as well as between mycetoma and other conditions. In eumycetoma, the grains produce numerous sharp bright hyper-reflective echoes. There are multiple thick-walled cavities with absence of acoustic enhancement. In actinomycetoma, the findings are similar but the grains are less distinct. The size and extent of the lesion can be accurately determined ultrasonically, a finding useful in planning surgical treatment.

MRI

This helps to assess bone destruction, periosteal reaction and particularly soft tissue involvement (Figure 6.29). MRI usually

Figure 6.29 Magnetic resonance imaging of foot showing multiple lesions of high signal intensity, which indicates granuloma, interspersed within a low-intensity matrix which is the fibrous tissue and the 'dot-in-circle sign', which indicates the presence of grains.

shows multiple 2–5 mm lesions of high signal intensity which indicates the granuloma, interspersed within a low-intensity matrix denoting the fibrous tissue. The 'dot-in-circle sign', which indicates the presence of grains, is highly characteristic.

CT scan

CT findings in mycetoma are not specific but are helpful to detect early bone involvement.

Histopathological diagnosis

Deep biopsy is obtained under general or regional anaesthesia although the chance of local spread is high. The biopsy should be adequate, contain grains and should be fixed immediately in 10 per cent formal saline.

Three types of host tissue reaction occur against the organism. In Type I, the grains are usually surrounded by a layer of polymorphonuclear leukocytes. The innermost neutrophils are closely attached to the surface of the grain, sometimes invading the grain causing its fragmentation. The hyphae and cement substance disappear and only remnants of brown pigmented cement are left behind. Outside the zone of neutrophils there is granulation tissue containing macrophages, lymphocytes, plasma cells and few neutrophils. The mononuclear cells increase in number towards the periphery of the lesion. The outermost zone of the lesion consists of fibrous tissue.

In Type II tissue reaction, the neutrophils largely disappear and are replaced by macrophages and multinucleated giant cells which engulf grain material. This consists largely of pigmented cement substance although hyphae are sometimes identified. Type III reaction is characterised by the formation of a well-organised epithelioid granuloma with Langhans' type giant cells. The centre of the granuloma sometimes contains remnants of fungal material.

Fine needle aspiration cytology

Fine needle aspiration cytology (FNAC) can yield an accurate diagnosis and helps in distinguishing between eumyc-

etoma and actinomycetoma. The technique is simple, rapid and sensitive.

Culture

A variety of microorganisms are capable of producing mycetoma. These can be identified by their textural description, morphological and biological activities in pure culture. Deep surgical biopsy is always needed to obtain the grains which are the source of culture. The grains extracted through the sinuses are usually contaminated and not viable and hence should be avoided. Several media may be used to isolate and grow these organisms.

In the absence of the classical triad of mycetoma, the demonstration of significant antibody titres against the causative organism may be of diagnostic value and for follow up. The common serodiagnostic tests are immunoelectrophoresis and ELISA (Summary box 6.16).

Summary box 6.16

Mycetoma – diagnosis

- Usually presents late as it is painless
- Triad of painless subcutaneous mass, multiple sinuses and seropurulent discharge
- Clinical picture may be deceptive as there may be deep-seated extension
- May spread to lymph nodes
- Can be confused with Kaposi's sarcoma
- Radiologically can be mistaken for osteosarcoma
- MRI shows typical 'dot-in-circle' sign
- Open biopsy and FNAC will be confirmatory

Management

Ideally, this should be a team effort between the physician and the surgeon. In actinomycetoma, combined drug therapy with amikacin sulphate and co-trimoxazole in the form of cycles is the treatment of choice. Amoxicillin-clavulanic acid, rifampacin, sulphonamides, gentamicin and kanamycin are used as a second line of treatment. Long-term drug treatment is beset with serious side effects.

In eumycetoma, ketoconazole, intraconazole and voriconazole are the drugs of choice. They may need to be used for up to a year. Use of these drugs should be closely monitored by the physician for side effects. While not being curative, these drugs help to localise the disease by forming thickly encapsulated lesions which are then amenable to surgical excision. Medical treatment for both types of mycetoma must continue until the patient is cured and also in the postoperative period.

Surgical treatment

Surgery is indicated in small localized lesions, resistance to medical treatment or for better response after medical treatment in patients with massive disease. Excision may need to be much more extensive than suggested at first on clinical appearance because the disease may extend to deeper planes which are not clinically apparent. The surgical options are wide local and debulking excisions and amputations. Amputation, used as a life-saving procedure, is indicated in advanced mycetoma refractory to medical treatment with severe secondary bacterial infection. The amputation rate is 10–25 per cent.

Postoperative medical treatment should continue for an adequate period to prevent recurrence. The recurrence rate varies from 25 to 50 per cent. This can be local or distant to regional lymph nodes. Recurrence is usually due to inadequate surgical excision, use of local anaesthesia, lack of surgical experience, non-compliance of drugs due to financial reasons and lack of health education (Summary box 6.17).

Summary box 6.17

Mycetoma – management

- Ideally combined management by physician and surgeon
- Medical treatment with appropriate long-term antibiotics
- In large lesions medical treatment to reduce the size followed by excision
- Beware of serious drug side effects
- Surgery in the form of wide excision and amputation as a life-saving procedure
- High recurrence rate

POLIOMYELITIS

Introduction

Poliomyelitis is an enteroviral infection that sadly still affects children in developing countries – this is in spite of effective vaccination having been universally available for several decades. The virus enters the body by inhalation or ingestion. Clinically, the disease manifests itself in a wide spectrum of symptoms – from a few days of mild fever and headache to the extreme variety consisting of extensive paralysis of the bulbar form that may not be compatible with life because of involvement of the respiratory and pharyngeal muscles.

Diagnosis

The disease targets the anterior horn cells causing lower motor neurone paralysis. Muscles of the lower limb are affected twice as frequently as those of the upper limb (Figures 6.30 and 6.31).

Figure 6.30 Polio affecting predominantly the upper limb muscles with wasting of the intercostal muscles.

Figure 6.31 (a and b) A 12-year-old patient with polio showing marked wasting of the left upper arm muscles with flexion contractures of the left knee and hip; there is equinus deformity of the foot (courtesy of Dr SM Lakhota and Dr PK Jain, Kolkata, India).

Fortunately, only 1–2 per cent of sufferers develop paralytic symptoms but, when they do occur, the disability causes much misery (Figure 6.32). When a patient develops fever with muscle weakness, Guillain–Barré syndrome needs to be excluded. The latter has sensory symptoms and signs, and cerebrospinal fluid (CSF) analysis should help to differentiate between the two conditions.

Management

Surgical management is directed mainly towards the rehabilitation of the patient who has residual paralysis, the operations being tailored to that particular individual's disability. Children especially may show improvement in their muscle function for up to two years after the onset of the illness. Thereafter, many patients learn to manage their disability by incorporating various manoeuvres ('trick movements') into their daily life. The surgeon must be cautious in considering such a patient for any form of surgery.

Surgical treatment in the chronic form of the disease is the domain of a highly specialised orthopaedic surgeon who needs

Figure 6.32 A young patient with polio showing paralysis of the lower limb and paraspinal muscles causing marked scoliosis and a deformed pelvis.

to work closely with the physiotherapist both in assessing and rehabilitating the patient. Operations are only considered after a very careful and detailed assessment of the patient's needs. A multidisciplinary team consisting of the orthopaedic surgeon, neurologist, physiotherapist, orthotist and the family, should decide upon the need for and advisability of any surgical procedure (Summary box 6.18).

A description of the operations for the various disabilities is beyond the scope of this book. The reader should therefore seek surgical details in a specialist textbook. In 2012, WHO has declared India a polio-free country.

Summary box 6.18

Poliomyelitis

- A viral illness that is preventable
- Presents with protean manifestations of fever, headache and muscular paralysis without sensory loss, more frequently affecting the lower limbs
- Treatment is mainly medical and supportive in the early stages
- Surgery should only be undertaken after very careful assessment as most patients learn to live with their disabilities
- Surgery is considered for the various types of paralysis in the form of tendon transfers and arthrodesis, which is the domain of a specialised orthopaedic surgeon

Georges Guillain, 1876–1961, Professor of Neurology, The Faculty of Medicine, Paris, France.

Jean Alexandre Barré, 1880–1967, Professor of Neurology, Strasbourg, France.

Guillain and Barré described this condition in a joint paper in 1916 while serving as Medical Officers in the French Army during the First World War.

TROPICAL CHRONIC PANCREATITIS

Introduction

Tropical chronic pancreatitis is a disease affecting the younger generation from poor socioeconomic strata in developing countries, seen mostly in southern India. The aetiology remains obscure with malnutrition, dietary, familial and genetic factors being possible causes. Alcohol ingestion does not play a part in the aetiology.

Aetiology and pathology

Cassava (tapioca) is a root vegetable that is readily available and inexpensive and is therefore consumed as a staple diet by people from a poor background. It contains derivatives of cyanide that are detoxified in the liver by sulphur-containing amino acids. The less well-off among the population lack such amino acids in the diet. This results in cyanogen toxicity causing the disease. Several members of the same family have been known to suffer from this condition; this strengthens the theory that cassava toxicity is an important cause because family members eat the same food.

Macroscopically, the pancreas is firm and nodular with extensive periductal fibrosis, with intraductal calcium carbonate stones of different sizes and shapes that may show branches and resemble a staghorn. The ducts are dilated. Microscopically, fibrosis is the predominant feature – intralobular, interlobular and periductal – with plasma cell and lymphocyte infiltration. There is a high incidence of pancreatic cancer in these patients (Summary box 6.19).

Summary box 6.19

Pathology of tropical chronic pancreatitis

- Almost exclusively occurs in developing countries and is due to malnutrition; alcohol is not a cause
- Cassava ingestion is regarded as an aetiological factor because of its high content of cyanide compounds
- Dilatation of pancreatic ducts with large intraductal stones
- Fibrosis of the pancreas
- A high incidence of pancreatic cancer in those affected by the disease

Diagnosis

The patient, usually male, is almost always below the age of 40 years and from a poor background. The clinical presentation is abdominal pain, thirst, polyuria and features of gross pancreatic insufficiency causing steatorrhoea and malnutrition. The patient looks ill and emaciated.

Initial routine blood and urine tests confirm that the patient has type 1 diabetes mellitus. This is known as fibrocalculous pancreatic diabetes, a label that is aptly descriptive of the typical pathological changes. Serum amylase is usually normal; in an acute exacerbation, it may be elevated. A plain abdominal x-ray shows typical pancreatic calcification in the form of discrete stones in the duct (Figure 6.33). Ultrasound and CT scanning of the pancreas confirm the diagnosis. An ERCP as an investigation should only be done when the procedure is also

Figure 6.33 Plain x-ray of the abdomen showing large stones along the main pancreatic duct typical of tropical chronic pancreatitis (courtesy of Dr V Mohan, Chennai, India).

being considered as a therapeutic manoeuvre for removal of ductal stones in the pancreatic head by papillotomy (Summary box 6.20).

Summary box 6.20

Diagnosis of tropical chronic pancreatitis

- The usual sufferer is a type 1 diabetic under 40 years of age
- Serum amylase may be elevated in an acute exacerbation
- Plain x-ray shows stones along the pancreatic duct
- Ultrasound and CT scan of the pancreas confirm the diagnosis
- ERCP may be used as a supplementary investigation and a therapeutic procedure

Treatment

The treatment is mainly medical with exocrine support using pancreatic enzymes, treatment of diabetes with insulin and the management of malnutrition. Treatment of pain should be along the lines of the usual analgesic ladder: non-opioids, followed by weak and then strong opioids and, finally, referral to a pain clinic.

Surgical treatment is necessary for intractable pain, particularly when there are stones in a dilated duct. Removal of the stones, with a side-to-side pancreaticojejunostomy to a Roux loop, is the procedure of choice. As most patients are young, pancreatic resection is only very rarely considered, and then only as a last resort, when all available methods of pain relief have been exhausted (Summary box 6.21).

Summary box 6.21**Treatment of tropical chronic pancreatitis**

- Mainly medical – pain relief, insulin for diabetes and pancreatic supplements for malnutrition
- Surgery is reserved for intractable pain
- Procedures are side-to-side pancreaticojejunostomy; resection in extreme cases

TUBERCULOSIS

While tuberculosis can affect all systems in the body, in the tropical developing world the surgeon is most often faced with tuberculosis affecting the cervical lymph nodes and the small intestine. Therefore in this chapter, tuberculous cervical lymphadenitis and tuberculosis of the small bowel will be described.

TUBERCULOUS CERVICAL LYMPHADENITIS**Introduction**

This is common in the Indian subcontinent. A young person who has recently arrived in the UK from an endemic area, presenting with cervical lymphadenopathy, should be diagnosed as having tuberculous lymphadenitis unless otherwise proven. With acquired immune deficiency syndrome (AIDS) being globally prevalent, this is not as rare in the West in the indigenous population as it used to be.

Diagnosis

Any of the cervical group of lymph nodes (jugulodigastric, sub-mandibular, supraclavicular, posterior triangle) can be involved.

Figure 6.34 Cervical tuberculous cold abscess about to burst (courtesy of Professor Ahmed Hassan Fahal, Khartoum, Sudan).

Figure 6.35 Cervical tuberculous sinus with typical overhanging edges (courtesy of Professor Ahmed Hassan Fahal, Khartoum, Sudan).

The patient has the usual general manifestations of tuberculosis: evening pyrexia, cough (maybe from pulmonary tuberculosis), malaise, and if the sufferer is a child, failure to thrive is a significant finding. Locally there will be regional lymphadenopathy where the lymph nodes may be matted; in late stages, a cold abscess may form – a painless, fluctuant, mass, not warm; significantly, there are no signs of inflammation (Figure 6.34), hence called a ‘cold abscess’. This is a clinical manifestation of underlying caseation.

Left untreated, the cold abscess initially deep to the deep fascia now bursts through into the space just beneath the superficial fascia. This produces a bilocular mass with cross fluctuation. This is called a ‘collar-stud’ abscess. Eventually, this may burst through the skin discharging pus and forming a tuberculous sinus (Figure 6.35). The latter typically has watery discharge with undermined edges (Summary box 6.22).

Summary box 6.22**Tuberculous cervical lymphadenitis**

- This is a common condition at any age
- Matted lymphnodal mass is the typical clinical feature
- In later stages the mass may be cystic denoting an abscess
- The abscess denotes underlying caseation and does not show any features of inflammation – hence called cold abscess
- Ultimately the abscess may burst forming a sinus
- Diagnosis is clinched by culture of pus and biopsy of the lymph node
- Involvement of other systems must be excluded
- Treatment is mainly medical

Collar-stud abscess is so called because it resembles a collar stud (which has two parts) used in shirts with detachable collars, now largely out of fashion.

Investigations

Raised ESR and CRP, low haemoglobin and a positive Mantoux test are usual, although the last is not significant in a patient from an endemic area. The Mantoux test (tuberculin skin test), although in use for over a hundred years, has now been superseded by interferon gamma (IFN- γ) release assays. This is an *in vitro* blood test of cellular immune response. Antigens unique to *Mycobacterium tuberculosis* are used to stimulate and measure T-cell release of IFN- γ . This helps to earmark patients who have latent or subclinical tuberculosis and thus benefit from treatment.

Sputum for culture and sensitivity (the result may take several weeks) and staining by the Ziehl–Neelsen method for acid-fast bacilli (the result is obtained much earlier) should also be done.

Specific investigations include aspiration of the pus in a cold abscess for culture and sensitivity. If the mass is still in the early stages of adenitis, excision biopsy should be done. Here, part of the lymph nodes should be sent fresh and unfixed to the laboratory who should be warned of the arrival of the specimen so that the tissue can be appropriately processed immediately.

Treatment

This must be a combined management between the physician and the surgeon. Tuberculous infection at other sites must be excluded and suitably managed. Medical treatment is the mainstay. The reader is asked to refer to details of medical treatment in an appropriate source.

TUBERCULOSIS OF SMALL INTESTINE

Introduction

Infection by *Mycobacterium tuberculosis* is common in the tropics. In these days of international travel and increased migration to the UK, tuberculosis in general and intestinal tuberculosis in particular are no longer clinical curiosities in the West. Any patient, particularly one who has recently arrived from an endemic area and who has features of generalised ill health and altered bowel habit, should arouse the suspicion of intestinal tuberculosis. The increased incidence of human immunodeficiency virus (HIV) infection worldwide has also made tuberculosis more common.

Pathology

When a patient with pulmonary tuberculosis swallows infected sputum, the organism colonises the lymphatics of the terminal ileum, causing transverse ulcers with typical undermined edges. The serosa is usually studded with tubercles. Histology shows caseating granuloma with giant cells (Figure 6.36). This pathological entity, referred to as the ulcerative type, denotes a severe form of the disease in which the virulence of the organism overwhelms host resistance.

The other variety, called the hyperplastic type, occurs when host resistance has the upper hand over the virulence of the organism. It is caused by the drinking of infected milk. There is a marked inflammatory reaction causing hyperplasia and thickening of the terminal ileum because of its abundance of lymphoid

Figure 6.36 Histology of ileocaecal tuberculosis. C: caseation. Black arrows show epithelioid granuloma with multi-nucleated giant cells. Yellow arrow shows acid-fast bacilli on Ziehl–Neelsen staining. (Courtesy of Dr Rosslyn Rankin, Raigmore Hospital, Inverness, Scotland.)

follicles, thus causing narrowing of the lumen and obstruction. In both types there may be marked mesenteric lymphadenopathy. Macroscopically, this type may be confused with Crohn's disease. The small intestine shows areas of stricture and fibrosis most pronounced at the terminal ileum (Figure 6.37). As a result, there is shortening of the bowel with the caecum being pulled up into a subhepatic position (Summary box 6.23).

Summary box 6.23

Tuberculosis – pathology

- Increasingly being seen in the UK, mostly among immigrants
- Two types are recognised – ulcerative and hyperplastic
- The ulcerative type occurs when the virulence of the organism is greater than the host defence
- The opposite occurs in the hyperplastic type
- Small bowel strictures are common in the hyperplastic type, mainly affecting the ileocaecal area
- In the ulcerative type, the bowel serosa is studded with tubercles
- Localised areas of ascites occur in the form of cocoons
- The lungs and other organs, particularly of the genitourinary system, may also be involved simultaneously

Clinical features

Patients present electively with weight loss, chronic cough, malaise, evening rise in temperature with sweating, vague abdominal pain with distension and alternating constipation and diarrhoea. As an emergency, they present with features of distal small bowel obstruction from strictures of the small bowel, particularly the terminal ileum. Rarely, a patient may present

Burrill Bernard Crohn, 1884–1983, gastroenterologist, Mount Sinai Hospital, New York, NY, USA, described regional ileitis in 1932 along with Leon Ginzburg and Gordon Oppenheimer.

Charles Mantoux, 1877–1947, physician, Le Cannet, Alpes Maritimes, France, described the intradermal tuberculin skin test in 1908.

Franz Heinrich Paul Ziehl, 1859–1926, neurologist, Lubeck, Germany.

Friedrich Carl Adolf Neelsen, 1854–1894, pathologist, Prosector, the Stadt-Krankenhaus, Dresden, Germany.

Figure 6.37 Emergency limited ileocolic resection: specimen showing tuberculous stricture in the terminal ileum and perforation of a transverse ulcer just proximal to the stricture.

with features of peritonitis from perforation of a tuberculous ulcer in the small bowel (Figure 6.37).

Examination shows a chronically ill patient with a 'doughy' feel to the abdomen from areas of localised ascites. In the hyperplastic type, a mass may be felt in the right iliac fossa. In addition, some patients may present with fistula-in-ano, which is typically multiple with undermined edges and watery discharge.

As this is a disease mainly seen in developing countries, patients may present late as an emergency from intestinal obstruction. Abdominal pain and distension, constipation and bilious and faeculent vomiting are typical of such a patient who is *in extremis*.

There may be features of other system involvement, such as the genitourinary tract, when the patient complains of frequency

of micturition. Clinical examination does not show any abnormality. The genitourinary tract should then be investigated (Summary box 6.24).

Summary box 6.24

Tuberculosis – clinical features

- Intestinal tuberculosis should be suspected in any patient from an endemic area who presents with weight loss, malaise, evening fever, cough, alternating constipation and diarrhoea and intermittent abdominal pain with distension
- The abdomen has a doughy feel; a mass may be found in the right iliac fossa
- The emergency patient presents with features of distal small bowel obstruction – abdominal pain, distension, bilious and faeculent vomiting
- Peritonitis from a perforated tuberculous ulcer in the small bowel can be another emergency presentation

Investigations

General investigations are the same as those for suspected tuberculosis anywhere in the body. They have been detailed in the previous section.

A barium meal and follow-through (or small bowel enema) shows strictures of the small bowel, particularly the ileum, typically with a high subhepatic caecum with the narrow ileum entering the caecum directly from below upwards in a straight line rather than at an angle (Figures 6.38 and 6.39a). Laparoscopy reveals the typical picture of tubercles on the bowel serosa, multiple strictures, a high caecum, enlarged lymph nodes, areas of caseation and ascites. Culture of the ascitic fluid may be helpful. A chest x-ray is essential (Figure 6.39b).

If the patient complains of urinary symptoms, urine is sent for microscopy and culture; the finding of sterile pyuria should alert

Figure 6.38 (a and b) Series of a barium meal and follow-through showing strictures in the ileum with the caecum pulled up into a subhepatic position.

Figure 6.39 Barium meal and follow-through (a) and chest x-ray (b) in a patient with extensive intestinal and pulmonary tuberculosis, showing ileal strictures with high caecum and pulmonary infiltration.

the clinician to the possibility of tuberculosis of the urinary tract, when the appropriate investigations should be done. A flexible cystoscopy would be very useful in the presence of sterile pyuria. A contracted bladder ('thimble' bladder) with ureteric orifices that are in-drawn ('golf-hole' ureter) may be seen; these changes are due to fibrosis.

In the patient presenting as an abdominal emergency, urea and electrolytes show evidence of gross dehydration. Plain abdominal x-ray shows typical small bowel obstruction – valvulae conniventes of dilated jejunum and featureless ileum with evidence of fluid between the loops (Summary box 6.25).

Summary box 6.25

Intestinal tuberculosis – investigations

- Raised inflammatory markers, anaemia and positive sputum culture
- Interferon-gamma release assays for subclinical infection is done
- Ultrasound of the abdomen may show localised areas of ascites
- Chest x-ray shows pulmonary infiltration
- Barium meal and follow-through shows multiple small bowel strictures particularly in the ileum with a subhepatic caecum
- If symptoms warrant, the genitourinary tract is also investigated

Treatment

On completion of medical treatment, the patient's small bowel is reimaged to look for significant strictures. If the patient has

features of subacute intermittent obstruction, bowel resection, in the form of limited ileocolic resection (Figure 6.37) with anastomosis between the terminal ileum and ascending colon, strictureplasty or right hemicolectomy, is performed as deemed appropriate. The surgical principles and options in the elective patient are very similar to those for Crohn's disease.

The emergency patient presents a great challenge. Such a patient is usually from a poor socioeconomic background, hence the late presentation of acute, distal, small bowel obstruction. The patient is extremely ill from dehydration, malnutrition, anaemia and probably active pulmonary tuberculosis. Vigorous resuscitation should precede the operation. At laparotomy, the minimum life-saving procedure is carried out, such as a side-to-side ileotransverse anastomosis for a terminal ileal stricture. If the general condition of the patient permits, a one-stage resection and anastomosis may be performed.

Thereafter, the patient should ideally be under the combined care of the physician and surgeon for a full course of anti-tuberculous chemotherapy and improvement in nutritional status; this may require three to six months of care. The patient who had a simple bypass procedure is reassessed and, when the disease is no longer active (as evidenced by return to normal of inflammatory markers, weight gain, negative sputum culture), an elective right hemicolectomy is done. This may be supplemented with strictureplasty for short strictures at intervals.

Perforation is treated by thorough resuscitation followed by resection of the affected segment. Anastomosis is performed provided it is regarded as safe to do so when peritoneal contamination is minimal and widespread disease is not encountered; otherwise, as a first stage, resection and exteriorisation is done followed by restoration of bowel continuity as a second stage

later on after a full course of anti-tuberculous chemotherapy and improvement in nutritional status (Summary box 6.26).

Summary box 6.26

Tuberculosis – treatment

- Patients should ideally be under the combined care of a physician and surgeon
- Vigorous supportive and full drug treatment is mandatory in all cases
- Symptomatic strictures are treated by the appropriate resection, e.g. local ileocolic resection or strictureplasty as an elective procedure once the disease is completely under control
- Acute intestinal obstruction from distal ileal stricture is treated by thorough resuscitation followed by side-to-side ileotransverse bypass
- Once the patient has recovered with medical treatment, then the second-stage definitive procedure of right hemicolectomy is done to remove the blind loop
- One-stage resection and anastomosis can be considered if the patient's general condition permits
- Perforation is treated by appropriate local resection and anastomosis or exteriorisation if the condition of the patient is very poor; this is later followed by restoration of bowel continuity after the patient has fully recovered with anti-tuberculous chemotherapy

Figure 6.40 Histology of enteric perforation of the small intestine showing erythrophagocytosis (arrows) with predominantly histiocytic proliferation (courtesy of Dr AK Mandal, New Delhi, India).

TYPHOID

Introduction

Typhoid fever is caused by *Salmonella typhi*, also called the typhoid bacillus. This is a Gram-negative organism. Like most infections occurring in developing countries in the tropics, the organism gains entry into the human gastrointestinal tract as a result of poor hygiene and inadequate sanitation. It is a disease normally managed by physicians, but the surgeon is called upon to treat the patient with typhoid fever because of perforation of a typhoid ulcer.

Pathology

Following ingestion of contaminated food or water, the organism colonises the Peyer's patches in the terminal ileum causing hyperplasia of the lymphoid follicles followed by necrosis and ulceration. The microscopic picture shows erythrophagocytosis with histiocytic proliferation (Figure 6.40). If the patient is left untreated or inadequately treated, the ulcers may lead to perforation and bleeding. The bowel may perforate at several sites including the large bowel.

Diagnosis

A typical patient is from an endemic area or who has recently visited such a country and suffers from a high temperature for 2–3 weeks. The patient may be toxic with abdominal distension from paralytic ileus. The patient may have melaena due to haemorrhage from a typhoid ulcer; this can lead to hypovolaemia.

Blood and stool cultures confirm the nature of the infection and exclude malaria. Although obsolete in the UK, the Widal

test is still done in the Indian subcontinent. The test looks for the presence of agglutinins to O and H antigens of *Salmonella typhi* and *paratyphi* in the patient's serum. In endemic areas, laboratory facilities may sometimes be limited. Certain other tests have been developed which identify sensitive and specific markers for typhoid fever. Practical and cheap kits are available for their rapid detection that need no special expertise and equipment. These are Multi-Test Dip-S-Ticks to detect immunoglobulin G (IgG), Tubex to detect immunoglobulin M (IgM) and TyphiDot to detect IgG and IgM. These tests are particularly valuable when blood cultures are negative (due to pre-hospital treatment or self-medication with antibiotics) or facilities for such an investigation are not available.

In the second or third week of the illness, if there is severe generalised abdominal pain, this heralds a perforated typhoid ulcer. The patient, who is already very ill, deteriorates further with classical features of peritonitis. An erect chest x-ray or a lateral decubitus film (in the very ill, as they usually are) will show free gas in the peritoneal cavity. In fact, any patient being treated for typhoid fever who shows a sudden deterioration accompanied by abdominal signs should be considered to have a typhoid perforation until proven otherwise (Summary box 6.27).

Summary box 6.27

Diagnosis of bowel perforation secondary to typhoid

- The patient presents in, or has recently visited, an endemic area
- The patient has persistent high temperature and is very toxic
- Positive blood or stool cultures for *Salmonella typhi* and the patient is already on treatment for typhoid
- After the second week, signs of peritonitis usually denote perforation, which is confirmed by the presence of free gas seen on x-ray

Daniel Elmer Salmon, 1850–1914, Veterinary Pathologist, Chief of the Bureau of Animal Industry, Washington DC, USA.

Johann Conrad Peyer, 1653–1712, Professor of Logic, Rhetoric and Medicine, Schaffhausen, Switzerland, described the lymph follicles in the intestine in 1677.

Georges Fernand Isidore Widal, 1862–1929, Professor of Internal Pathology, and later of Clinical Medicine, Faculty of Medicine, Paris, France. He developed the test in 1896 to diagnose typhoid fever.

Treatment

Vigorous resuscitation with intravenous fluids and antibiotics in an intensive care unit gives the best chance of stabilising the patient's condition. Metronidazole, cephalosporins and gentamicin are used in combination. Chloramphenicol, despite its potential side effect of aplastic anaemia, is still used occasionally in developing countries. Laparotomy is then carried out.

Several surgical options are available, and the most appropriate operative procedure should be chosen judiciously depending upon the general condition of the patient, the site of perforation, the number of perforations and the degree of peritoneal soiling. The alternatives are closure of the perforation (Figure 6.41) after freshening the edges, wedge resection of the ulcer area and closure, resection of bowel with or without anastomosis (exteriorisation), closure of the perforation and side-to-side ileotransverse anastomosis, ileostomy or colostomy where the perforated bowel is exteriorised after refashioning the edges. After closing an ileal perforation, the surgeon should look for other sites of perforation or necrotic patches in the small or large bowel that might imminently perforate, and deal with them appropriately. Thorough peritoneal lavage is essential. The linea alba is closed leaving the rest of the abdominal wound open for delayed closure, as wound infection is almost inevitable and dehiscence not uncommon. In the presence of rampant infection, laparostomy may be a good alternative.

Figure 6.41 (a and b) Typhoid perforation of the terminal ileum.

When a typhoid perforation occurs within the first week of illness, the prognosis is better than if it occurs after the second or third week because, in the early stages, the patient is less nutritionally compromised and the body's defences are more robust. Furthermore, the shorter the interval between diagnosis and operation, the better is the prognosis (Summary box 6.28).

Summary box 6.28

Treatment of bowel perforation from typhoid

- Manage in intensive care
- Resuscitate and give intravenous antibiotics
- Laparotomy – choice of various procedures
- Most common site of perforation is the terminal ileum
- Having found a perforation, always look for others
- In the very ill patient, consider some form of exteriorisation
- Close the peritoneum and leave the wound open for secondary closure

Principles of laparoscopic and robotic surgery

LEARNING OBJECTIVES

To understand:

- The principles of laparoscopic and robotic surgery
- The advantages and disadvantages of such surgery
- The safety issues and indications for laparoscopic and robotic surgery
- The principles of postoperative care

DEFINITION

Minimal access surgery is a marriage of modern technology and surgical innovation that aims to accomplish surgical therapeutic goals with minimal somatic and psychological trauma. This type of surgery has reduced wound access trauma, as well as being less disfiguring than conventional techniques. With increasing experience, it offers cost-effectiveness both to health services and to employers by shortening operating times, shortening hospital stays and allowing faster recuperation.

EXTENT OF MINIMAL ACCESS SURGERY

Minimal access surgery has crossed all traditional boundaries of specialties and disciplines. Shared, borrowed and overlapping technologies and information are encouraging a multidisciplinary approach that serves the whole patient, rather than a specific organ system. Broadly speaking, minimal access techniques can be categorised as follows.

Laparoscopy

A rigid endoscope (laparoscope) is introduced through a port into the peritoneal cavity. This is insufflated with carbon dioxide to produce a pneumoperitoneum. Further ports are inserted to enable instrument access and their use for dissection (Figure 7.1). There is little doubt that laparoscopic cholecystectomy has revolutionised the surgical management of cholelithiasis and has become the mainstay of management of uncomplicated gallstone disease. With improved instrumentation, advanced procedures, such as laparoscopic colectomies for malignancy, previously regarded as controversial, have also become fully accepted. There has been an increasing evidence base showing the short-term benefits of laparoscopic surgery over open surgery with regards to postoperative pain, length of stay, earlier return to normal activities, but maintaining equivalence of the benefits of the long-term outcomes, such as oncological quality and cancer-related survival.

Figure 7.1 Basic laparoscopic instruments (photo courtesy of Daniel Leff).

Thoracoscopy

A rigid endoscope is introduced through an incision in the chest to gain access to the thoracic contents. Usually there is no requirement for gas insufflation as the operating space is held open by the rigidity of the thoracic cavity.

Endoluminal endoscopy

Flexible or rigid endoscopes are introduced into hollow organs or systems, such as the urinary tract, upper or lower gastrointestinal tract, and respiratory and vascular systems (see Chapter 14).

Perivisceral endoscopy

Body planes can be accessed even in the absence of a natural cavity. Examples are mediastinoscopy, retroperitoneoscopy and retroperitoneal approaches to the kidney, aorta and lumbar sympathetic chain. Extraperitoneal approaches to the retroperitoneal organs, as well as hernia repair, are now becoming

increasingly commonplace, further decreasing morbidity associated with visceral peritoneal manipulation. Other, more recent, examples include subfascial ligation of incompetent perforating veins in varicose vein surgery.

Arthroscopy and intra-articular joint surgery

Orthopaedic surgeons have long used arthroscopic access to the knee and have now moved their attention to other joints, including the shoulder, wrist, elbow and hip.

Combined approach

The diseased organ is visualised and treated by an assortment of endoluminal and extraluminal endoscopes and other imaging devices.

SURGICAL TRAUMA IN OPEN, LAPAROSCOPIC AND ROBOTIC SURGERY

Most of the trauma of an open procedure is inflicted because the surgeon must have a wound that is large enough to give adequate exposure for safe dissection at the target site. The wound is often the cause of morbidity, including infection, dehiscence, bleeding, herniation and nerve entrapment. Wound pain prolongs recovery time and, by reducing mobility, contributes to an increased incidence of pulmonary atelectasis, chest infection, paralytic ileus and deep venous thrombosis.

Mechanical and human retractors cause additional trauma. Body wall retractors tend to inflict localised damage that may be as painful as the wound itself. In contrast, during laparoscopy, the retraction is provided by the low-pressure pneumoperitoneum, giving a diffuse force applied gently and evenly over the whole body wall, causing minimal trauma.

Exposure of any body cavity to the atmosphere also causes morbidity through cooling and fluid loss by evaporation. There is also evidence to suggest that the incidence of post-surgical adhesions has been reduced by the use of the laparoscope because there is less damage to delicate serosal coverings. In handling intestinal loops, the surgeon and assistant disturb the peristaltic activity of the gut and provoke adynamic ileus.

Minimal access surgery has many advantages, such as a reduction in the trauma of access and exposure and an improvement in visualisation (Summary box 7.1).

Summary box 7.1

Advantages of minimal access surgery

- Decrease in wound size
- Reduction in wound infection, dehiscence, bleeding, herniation and nerve entrapment
- Decrease in wound pain
- Improved mobility
- Decreased wound trauma
- Decreased heat loss
- Improved vision

LIMITATIONS OF MINIMAL ACCESS SURGERY

Despite its many advantages, minimal access surgery has its limitations. To perform minimal access surgery with safety, the surgeon must operate remote from the surgical field, using an imaging system that provides a two-dimensional representation of the operative site. The endoscope offers a whole new anatomical landscape, which the surgeon must learn to navigate without the usual clues that make it easy to judge depth. The instruments are longer and sometimes more complex to use than those commonly used in open surgery. This results in the novice being faced with significant problems of hand-eye coordination.

Some of the procedures performed by these new approaches are more technically demanding and are slower to perform and often have a more difficult learning curve as tactile feedback to the surgeon is lost. Indeed, on occasion, a minimally invasive operation is so technically demanding that both patient and surgeon are better served by conversion to an open procedure. Unfortunately, there seems to be a sense of shame associated with conversion, which is quite unjustified. It is vital for surgeons and patients to appreciate that the decision to close or convert to an open operation is not a complication but, instead, usually implies sound surgical judgement.

Another problem occurs when there is intraoperative arterial bleeding. Haemostasis may be very difficult to achieve endoscopically because blood obscures the field of vision and there is a significant reduction of the image quality owing to light absorption.

Another disadvantage of laparoscopic surgery is the loss of tactile feedback; this is an area of ongoing research in haptics and biofeedback systems. Early work suggested that laparoscopic ultrasonography might be a substitute for the need to 'feel' in intraoperative decision-making. The rapid progress in advanced laparoscopic techniques, including biliary tract exploration and surgery for malignancies, has provided a strong impetus for the development of laparoscopic ultrasound. Now more developed over the last decade, this technique already has advantages that far outweigh its disadvantages.

In more advanced techniques, large pieces of resected tissue, such as the lung or colon, may have to be extracted from the body cavity. Occasionally, the extirpated tissue may be removed through a nearby natural orifice, such as the rectum, or the mouth. At other times, a novel route may be employed. For instance, a benign colonic specimen may be extracted through an incision in the vault of the vagina. Several innovative tube systems have been shown to facilitate this extraction. Although tissue 'morcellators, mincers and liquidisers' can be used in some circumstances, they have the disadvantage of reducing the amount of information available to the pathologist. Previous reports of tumour implantation in the locations of port sites raised important questions about the future of the laparoscopic treatment of malignancy, but large-scale trials have shown this claim to be false. Although emerging evidence from large-scale international prospective trials implicate surgical skill as an important aetiological factor, it is important to consider the biological implications of minimally invasive strategies on the tumours. The use of carbon dioxide and helium as insufflants causes locoregional hypoxia and may also change pH. The

resultant modulation of spilled tumour cell behaviour is only now being elucidated.

Hand-assisted laparoscopic surgery is a well-developed technique. It involves the intra-abdominal placement of a hand or forearm through a minilaparotomy incision, while pneumoperitoneum is maintained. In this way, the surgeon's hand can be used as in an open procedure. It can be used to palpate organs or tumours, reflect organs atraumatically, retract structures, identify vessels, dissect bluntly along a tissue plane and provide finger pressure to bleeding points, while proximal control is achieved. In addition, several reports have suggested that this approach is more economical than a totally laparoscopic approach, reducing both the number of laparoscopic ports and the number of instruments required. Some advocates of the technique claim that it is also easier to learn and perform than totally laparoscopic approaches, and that there may be increased patient safety.

There is a growing need for improvement in dissection techniques in laparoscopic surgery and, specifically, for improving the safe use of electrosurgery and lasers. Ultrasonic dissection, tissue fusion devices and tissue removal have been utilised by a growing number of specialties for several years. The adaptation of the technology to laparoscopic surgery grew out of the search for alternative, possibly safer, methods of dissection. The current units combine the functions of three or four separate instruments, reducing the need for instrument exchanges during a procedure. This flexibility, combined with the ability to provide a clean, smoke-free field, improves safety while shortening operating times.

Although dramatic cost savings are possible with laparoscopic cholecystectomy, the position was less clear-cut with other procedures initially. There is another factor that may complicate the computation of the cost-benefit ratio. A significant rise in the rate of cholecystectomy followed the introduction of the laparoscopic approach as the threshold for referring patients for surgery lowered. The increase in the number of procedures performed has led to an overall increase in the cost of treating symptomatic gallstones.

Three-dimensional imaging systems are available, but remain expensive and currently are not commonplace. Stereoscopic imaging for laparoscopy is still progressing. Future improvements in these systems will greatly enhance manipulative ability in critical procedures, such as knot tying and dissection of closely underlying tissues. There are, however, some drawbacks, such as reduced display brightness and interference with normal vision because of the need to wear specially designed glasses for some systems. It is likely that brighter projection displays will be developed, at increased cost. However, the need to wear glasses will not be easily overcome.

Looking further to the future, it is evident that the continuing reductions in the costs of elaborate image-processing techniques will result in a wide range of transformed presentations becoming available. It will ultimately be possible for a surgeon to call up any view of the operative region that is accessible to a camera and present it stereoscopically in any size or orientation, superimposed on past images taken in other modalities. Such augmented reality systems are being developed at present, but are currently in relative infancy. It is for the medical community to decide which of these many potential imaginative techniques will contribute most to effective surgical procedures (Summary box 7.2).

Summary box 7.2

Limitations of minimal access surgery

- Reliance on remote vision and operating
- Loss of tactile feedback
- Dependence on hand-eye coordination
- Difficulty with haemostasis
- Reliance on new techniques
- Extraction of large specimens

ROBOTIC SURGERY

A robot is a mechanical device that performs automated physical tasks according to direct human supervision, a predefined program or a set of general guidelines using artificial intelligence techniques. In terms of surgery, robots have been used to assist surgeons during procedures. This has been primarily in the form of automated camera systems and telemanipulator systems, thus resulting in the creation of a human-machine interface.

Even though laparoscopic surgery has progressed greatly over the last two decades, there are limitations. These include the restriction to two-dimensional views, reduced degrees of freedom of movement, little or no tactile feedback and ergonomically difficult positions for the surgeon. Such problems undoubtedly affect surgical precision. This has led to interest in robotic master-slave systems (where the surgeon is the master, i.e. the operator, and the robot is the slave). Such devices have been under trial during the last ten years. They offer many benefits, which have arisen as a result of new technology in lenses, cameras and computer software. The advantages are two-fold: first for the patient (as for laparoscopic surgery, Summary box 7.1) and second for the surgeon. The advantages for the surgeon include better visualisation (higher magnification) with stereoscopic views; elimination of hand tremor allowing greater precision; improved manoeuvring as a result of the 'robotic wrist', which allows seven degrees of freedom; and the fact that large external movements of the surgical hands can be scaled down and transformed to limited internal movements of the 'robotic hands', extending the surgical ability to perform complex technical tasks in a limited space. Also, the surgeon is able to work in an ergonomic environment with less stress and achieve higher levels of concentration. The computer may also be able to compensate for the beating movement of the heart, making it unnecessary to stop the heart during cardiothoracic surgery. There may also be less need for assistance once surgery is under way.

Many surgical specialties have embraced the progression of robot-assisted techniques, including general surgery, cardiothoracic surgery, urology, orthopaedics, ear, nose and throat (ENT) surgery and paediatric surgery. Specialities that use microsurgical techniques will particularly benefit in the future.

There are different robotic systems available (see Figures 7.2, 7.3, 7.4 and 7.5). Robotic camera systems include AESOP (Computer Motion, Goleta, CA, USA) and EndoAssist (Armstrong Healthcare, High Wycombe, UK). Telerobotic manipulators include the da Vinci (Intuitive Surgical, Menlo Park, CA, USA) and ZEUS (Computer Motion) manipulators. Finally, telerobotics and telementoring has been combined in systems such as SOCRATES (Computer Motion). All of these systems offer different advantages to the operating surgeon,

Figure 7.2 da Vinci manipulators used during robotic laparoscopic cholecystectomy. This demonstrates the robotic grasper holding and retracting the gall bladder neck, while the robotic hook is used to free the overlying omentum on the gall bladder and cystic duct (courtesy of the Department of Biosurgery and Surgical Technology, Imperial College, London).

ranging from reducing the need for assistants and providing better ergonomic operating positions to providing experienced guidance from surgeons not physically present in the operating theatre.

PREOPERATIVE EVALUATION

Preparation of the patient

Although the patient may be in hospital for a shorter period, careful preoperative management is essential to minimise morbidity.

History

Patients must be fit for general anaesthesia and open operation if necessary. Potential coagulation disorders (e.g. associated with cirrhosis) are particularly dangerous in laparoscopic surgery. As adhesions may cause problems, previous abdominal operations or peritonitis should be documented.

Examination

Routine preoperative physical examination is required as for any major operation. Although, in general, laparoscopic surgery allows quicker recovery, it may involve longer operating times and the establishment of the pneumoperitoneum may provoke cardiac arrhythmias. Severe chronic obstructive airways disease and ischaemic heart disease may be contraindications to the laparoscopic approach.

Particular attention should be paid to the presence or absence of jaundice, abdominal scars, palpable masses or tenderness.

Moderate obesity does not increase operative difficulty significantly, but massive obesity may make pneumoperitoneum difficult and standard instrumentation may be too short. Access may prove difficult in very thin patients, especially those with severe kyphosis.

Premedication

Premedication is the responsibility of the anaesthetist, with whom coexisting medical problems should be discussed.

Prophylaxis against thromboembolism

Venous stasis induced by the reverse Trendelenburg position during laparoscopic surgery may be a particular risk factor for deep vein thrombosis, as is a lengthy operation and the obesity of many patients. Subcutaneous low molecular weight heparin and antithrombotic stockings should be used routinely in addition to pneumatic leggings during the operation. Patients already taking warfarin for other reasons should have this stopped temporarily or converted to intravenous heparin, depending on the underlying condition, as it is not safe to perform laparoscopic surgery in the presence of a significant coagulation deficit.

Urinary catheters and nasogastric tubes

In the early days of laparoscopic surgery, routine bladder catheterisation and nasogastric intubation were advised. Most surgeons now omit these, but it remains essential to check that the patient is fasted and has recently emptied the bladder, particularly before the blind insertion of a Verres needle. However, currently, most general surgeons prefer the direct cut-down technique into the abdomen for the introduction of the first port for the establishment of the pneumoperitoneum (Hasson technique). More recently, direct optical entry has been used especially in the setting of bariatric surgery.

Informed consent

The basis of many complaints and much litigation in surgery, especially laparoscopic surgery, relates to the issue of informed consent. It is essential that the patient understands the nature of the procedure, the risks involved and, when appropriate, the alternatives that are available. A locally prepared explanatory booklet concerning the laparoscopic procedure to be undertaken is extremely useful.

In an elective case, a full discussion of the proposed operation should take place in the outpatient department with a surgeon of appropriate seniority, preferably the operating surgeon, before the decision is made to operate. On admission, it is the responsibility of the operating surgeon and anaesthetist to ensure that the patient has been fully counselled, although the actual witnessing of the consent form may have been delegated. The patient should understand what laparoscopic surgery involves and that there is a risk of conversion to open operation. If known, this risk should be quantified, for example the increased risk with acute cholecystitis or in the presence of extensive upper abdominal adhesions. The conversion rate will also vary with the experience and practice of the surgeon. Common complications should be mentioned, such as shoulder tip pain and minor surgical emphysema, as well as rare but serious complications, including injury to the bile ducts and visceral injury from trocar insertion or diathermy.

A few patients may insist on having an open procedure (probably influenced by accounts of mishaps) and the surgeon should be prepared to offer this, although most will opt for laparoscopy if the surgeon has extensive experience and an impressive safety record.

When obtaining consent for robotic surgery, patients should be offered appropriate literature so that they are able to provide fully informed consent. As these procedures are still not routine, this should be carried out by the operating surgeon and, if the procedure is in the context of a clinical trial, the appropriate ethical approval and subsequent paperwork should be available to the patient before signing the consent form (Summary box 7.3).

Summary box 7.3

Preparation for laparoscopic or robotic surgery

- Overall fitness: cardiac arrhythmia, emphysema, medications, allergies
- Previous surgery: scars, adhesions
- Body habitus: obesity, skeletal deformity
- Normal coagulation
- Thromboprophylaxis
- Informed consent

Preparation is very similar to that for open surgery and aims to ensure that:

- The patient is fit for the procedure.
- The patient is fully informed and has consented.
- Operative difficulty is predicted when possible.
- Appropriate theatre time and facilities are available (especially important for robotic cases).

THEATRE SET UP AND TOOLS

Operating theatre design, construction and layout is key to its smooth running on a daily basis. Originally, the video and diathermy equipment and other key tools used in laparoscopic surgery were moved around on stacks, taking up valuable floor space and cluttering up the theatre environment, which was not always ergonomic for the operating team. New theatres are designed with moveable booms that come down from the ceiling; these are easy to place and do not have long leads or wires trailing behind them (Figure 7.6). The equipment consists of at least two high-resolution LCD monitors (and, more recently, high definition (HD) monitors for even clearer images), the laparoscopic kit for maintaining pneumoperitoneum and the audiovisual kit. The advent of DVD and other digital recording equipment has also led to these being incorporated into the rigs so that cases can be recorded with ease. This is further facilitated by cameras being inserted into the light handles of the main overhead lights so that open surgery can also be recorded without distracting the surgeons.

Image quality is vital to the success of laparoscopic surgery. New camera and lens technology allows the use of smaller cameras. Many centres now use 5-mm laparoscopes routinely. Automatic focusing and charge-coupled devices (CCDs) are used to detect different levels of brightness and adjust for the best image possible. Flat panel monitors with HD images are used to give the surgeon the best views possible and three-dimensional technology is now starting to be used for visualisation more

Figure 7.6 Modern laparoscopic theatre set up (photo courtesy of Daniel Leff).

routinely in some centres. The usability of the kit has also improved; touch screen panels and even voice-activated systems are now available on the market.

As minimally invasive and robotic procedures have become routine in some institutions, the dedicated theatre team for such procedures has also evolved. Surgeons and anaesthetists, as well as scrub and circulating nurses, have become familiar with working with the equipment and each other. The efficient working of the team is crucial to high-quality surgery and quick yet safe turnover times. Laparoscopic tools have also changed. Disposable equipment is more readily available, which does unfortunately increase the cost of the surgery. However, easy to use, ergonomically designed and reliable surgical tools are essential for laparoscopic and robotic surgery. Simple designs for new laparoscopic ports are now being studied, with the aim of reducing the incidence of port-site hernias; see-through (optical) ports that allow the surgeon to cut down through the abdomen while observing the layers through the cameras, and new light sources within the abdomen may be simple ideas that affect surgical technique in the near future.

GENERAL INTRAOPERATIVE PRINCIPLES

Laparoscopic cholecystectomy is now the 'gold standard' for operative treatment of symptomatic gallstone disease. The main negative aspect of the technique is the increased incidence of bile duct injury compared with open cholecystectomy. Better understanding of the mechanisms of injury, coupled with proper training, will avoid most of these errors. The following sections highlight the important technical steps that should be taken during any form of laparoscopic surgery to avoid complications.

Creating a pneumoperitoneum

There are two methods for creation of a pneumoperitoneum: open and closed. The closed method involves blind puncture using a Verres needle. Although this method is fast and relatively safe, there is a small but significant potential for intestinal or vascular injury on introduction of the needle or first trocar. The routine use of the open technique for creating a pneumoperitoneum avoids the morbidity related to a blind puncture. To achieve this, a 1-cm vertical or transverse incision is made at the level of the umbilicus. Two small retractors are used to

dissect bluntly the subcutaneous fat and expose the midline fascia. Two sutures are inserted each side of the midline incision, followed by the creation of a 1-cm opening in the fascia. Free penetration into the abdominal cavity is confirmed by the gentle introduction of a finger. Finally, a Hasson trocar (or other blunt-tip trocar) is inserted and anchored with the fascial sutures (Figure 7.7). The open technique may initially appear time-consuming and even cumbersome; however, with practice, it is quick, efficient and safe overall. Optical entry to the abdomen under direct vision using optical ports (especially in bariatric surgery) is gaining favour with many laparoscopic surgeons. This allows quick and safe entry to the peritoneal cavity using bladeless see-through trocars that allow the different layer to be dissected through using the laparoscope within an optical port to be inserted into the abdomen.

Figure 7.7 Open technique with Hasson port. Apply safe principles of closed technique.

Preoperative problems

Previous abdominal surgery

Previous abdominal surgery is no longer a contraindication to laparoscopic surgery, but preoperative evaluation is necessary to assess the type and location of surgical scars. As mentioned earlier, the open technique for insertion of the first trocar is safer. Before trocar insertion, the introduction of a fingertip helps to ascertain penetration into the peritoneal cavity and also allows adhesions to be gently removed from the entry site. After the tip of the cannula has been introduced, a laparoscope is used as a blunt dissector to tease adhesions gently away and form a tunnel towards the quadrant where the operation is to take place. This step is accomplished by a careful pushing and twisting motion under direct vision. With experience, the surgeon learns to differentiate visually between thick adhesions that may contain bowel and should be avoided and thin adhesions that would lead to a window into a free area of the peritoneal cavity (Figure 7.8).

Obesity

Laparoscopic and robotic surgery have proved to be safe and effective procedures in the obese population. In fact, some procedures are less difficult than their open counterparts for the

Figure 7.8 Intra-abdominal adhesion.

morbidly obese patient, e.g. in bariatric surgery. Technical difficulties occur, however, in obtaining pneumoperitoneum, reaching the operative region adequately and achieving adequate exposure in the presence of an obese colon. Increased thickness of the subcutaneous fat makes insufflation of the abdominal cavity more difficult. With the closed technique, a larger Verres needle is often required for morbidly obese patients. Pulling the skin up for fixation of the soft tissues is better accomplished with towel clamps. Only moderate force should be used to avoid separating the skin farther away from the fascia. The needle should be passed at nearly a right angle to the skin and preferably above the umbilicus where the peritoneum is more firmly fixed to the midline. The open technique of inserting a Hasson trocar is easier and safer for obese patients, but technically demanding in morbidly obese patients, where optical entry is now more commonplace. The main difficulty is reaching the fascia. A larger skin incision (1–3 cm), starting at the umbilicus and extending superiorly, may facilitate this. To reach the operative area adequately, the location of some of the ports has to be modified and, in some instances, larger and longer instruments are necessary. When the length of the laparoscope appears to be insufficient to reach the operative area adequately, the initial midline port should be placed nearer to the operative field. Recently, the use of optical port entry for laparoscopic bariatric surgery has revolutionised port entry for morbid obesity cases.

Operative problems

Intraoperative perforation of the gall bladder

Perforation of the gall bladder is more common with the laparoscopic technique than with the open technique (see also Chapter 67). Some authors have reported an incidence of up to 30 per cent, but it does not appear to be a factor in increasing the early postoperative morbidity. However, it is well known that bile is not a sterile fluid and bacteria can be present in the absence of cholecystitis. Unless the perforation is small, closure with endoloops or endoclips should be attempted to avoid contamination prior to extraction which should be with the use of an endobag. If there is stone spillage, every attempt must be made to collect and extract the stones and if there is a possibility of stones retained in the peritoneum, then an ultrasound should

be arranged 6 weeks postoperatively to assess a collection around a stone and the patient should be informed of this outcome postoperatively.

Bleeding

In some of the larger series, bleeding has been the most common cause for conversion to an open procedure. Bleeding plays a more important role in laparoscopic surgery because of factors inherent to the technique. These include a limited field that can easily be obscured by relatively small amounts of blood, magnification that makes small arterial bleeding appear to be a significant haemorrhage and light absorption that obscures the visual field.

How to avoid bleeding

As in any surgical procedure the best way to handle intraoperative bleeding is to prevent it from happening. This can usually be accomplished by identifying patients at high risk of bleeding, having a clear understanding of the laparoscopic anatomy and employing careful surgical technique.

Risk factors that predispose to increased bleeding include:

- cirrhosis;
- inflammatory conditions (acute cholecystitis, diverticulitis);
- patients on clopidogrel and or dipyridamole
- coagulation defects: these are contraindications to a laparoscopic procedure.

Bleeding from a major vessel

Damage to a large vessel requires immediate assessment of the magnitude and type of bleeding. When the bleeding vessel is identified, a fine-tip grasper can be used to grasp it and apply either electrocautery or a clip, depending on its size. When the vessel is not identified early and a pool of blood forms, compression should be applied immediately with a blunt instrument, a cotton swab (ENT or mastoid swab) or with the adjacent organ. Good suction and irrigation are of utmost importance. Once the area has been cleaned, pressure should be released gradually to identify the site of bleeding. Insertion of an extra port may be required to achieve adequate exposure and at the same time to enable the concomitant use of a suction device and an insulated grasper. Although most of the bleeding vessels can be controlled laparoscopically, judgement should be used in deciding when not to prolong bleeding, but to convert to an open procedure at an early stage. Surgicell or other clot-promoting strips, or tissue glues may also be used laparoscopically to aid haemostasis. If at any stage bleeding is difficult to stem laparoscopically, then there should be no delay to convert to open in the interests of patient safety.

Bleeding from the gall bladder bed

Bleeding from the gall bladder bed can usually be prevented by performing the dissection in the correct plane. When a bleeding site appears during detachment of the gall bladder, the dissection should be carried a little farther to adequately expose the bleeding point. Once this step has been performed, direct application of electrocautery usually controls the bleeding. If bleeding persists, indirect application of electrocautery is useful because it avoids detachment of the formed crust. This procedure is accomplished by applying pressure to the bleeding point with a blunt, insulated grasper and then applying electrocoagulation

by touching this grasper with a second insulated grasper that is connected to the electrocautery device. One must be careful to keep all conducting surfaces of the graspers within the visual field while applying the electrocautery current.

Bleeding from a trocar site

Bleeding from the trocar sites is usually controlled by applying upwards and lateral pressure with the trocar itself. Considerable bleeding may occur if the falciform ligament is impaled with the substernal trocar or if one of the epigastric vessels is injured. If significant continuous bleeding from the falciform ligament occurs, haemostasis is achieved by percutaneously inserting a large, straight needle at one side of the ligament. A monofilament suture attached to the needle is passed into the abdominal cavity and the needle is exited at the other side of the ligament using a grasper (Figure 7.9). The loop is suspended and compression is achieved. Maintaining compression throughout the procedure usually suffices. After the procedure has been completed, the loop is removed under direct laparoscopic visualisation to ensure complete haemostasis. When significant continuous bleeding from the abdominal wall occurs, haemostasis can be accomplished either by pressure or by suturing the bleeding site. Pressure can be applied using a Foley balloon catheter. The catheter is introduced into the abdominal cavity through the bleeding trocar site wound, the balloon is inflated and traction is placed on the catheter, which is bolstered in place to keep it under tension. The catheter is left *in situ* for 24 hours and then removed. Although this method is successful in achieving haemostasis, the authors favour direct suturing of the bleeding vessel. This manoeuvre is accomplished by extending the skin incision by 3 mm at both ends of the bleeding trocar site wound. Two figure-of-eight sutures are placed in the path of the vessel at both ends of the wound. Devices such as the EndoClose may also be used to apply transabdominal sutures under direct laparoscopic view to close port sites that bleed.

Evacuation of blood clots

The best way of dealing with blood clots is to avoid them. As mentioned, careful dissection and identification of the cystic artery and its branches, as well as identifying and carrying out dissection of the gall bladder in the correct plane, help to prevent bleeding from the cystic vessels and the hepatic bed. Nevertheless, clot formation takes place when unsuspected bleeding occurs or when inflammation is severe and a clear

plane is not present between the gall bladder and the hepatic bed. The routine use of 5000–7000 units of heparin per litre of irrigation fluid helps to avoid the formation of clots. When extra bleeding is foreseen, a small pool of irrigation fluid can be kept in the operative field to prevent clot formation. After clots have formed, a large bore suction device should be used for their retrieval. Care should be taken to avoid suctioning in proximity to placed clips.

Principles of electrosurgery during laparoscopic surgery

Electrosurgical injuries during laparoscopy are potentially serious. The vast majority occur following the use of monopolar diathermy. The overall incidence is between one and two cases per 1000 operations. Electrical injuries are usually unrecognised at the time that they occur, with patients commonly presenting 3–7 days after injury with complaints of fever and abdominal pain. As these injuries usually present late, the reasons for their occurrence are largely speculative. The main theories are: (1) inadvertent touching or grasping of tissue during current application; (2) direct coupling between a portion of bowel and a metal instrument that is touching the activated probe (Figure 7.10); (3) insulation breaks in the electrodes; (4) direct sparking to bowel from the diathermy probe; and (5) current passage to the bowel from recently coagulated, electrically isolated tissue. Bipolar diathermy is safer and should be used in preference to monopolar diathermy, especially in anatomically crowded areas. If monopolar diathermy is to be used, important safety measures include attainment of a perfect visual image, avoiding excessive current application and meticulous attention to insulation. Alternative methods of performing dissection, such as the use of ultrasonic devices, may improve safety.

Postoperative care

The postoperative care of patients after laparoscopic surgery is generally straightforward with a low incidence of pain or other problems. The most common routine postoperative symptoms are a dull upper abdominal pain, nausea and pain around the shoulders (referred from the diaphragm). There has been some suggestion that the instillation of local anaesthetic to the operating site and into the suprahepatic space, or even leaving 1 litre of normal

Figure 7.9 Port-side bleeding controlled with sutures.

Figure 7.10 Direct coupling between bowel and laparoscope, which is touching the activated probe.

saline in the peritoneum, serves to further decrease postoperative pain. It is a good general rule that if the patient develops a fever or tachycardia or complains of severe pain at the operation site, something is wrong and close observation is necessary. In this case, routine investigation should include a full blood count, C reactive protein (CRP) measurement, liver function tests, an amylase test and, probably, an ultrasound scan of the upper abdomen to detect fluid collections. If bile duct leakage is suspected, endoscopic retrograde cholangiopancreatography (ERCP) may be needed. If in doubt, relaparoscopy or laparotomy should be performed earlier rather than later. Death following technical errors in laparoscopic cholecystectomy has often been associated with a long delay in deciding to re-explore the abdomen.

In the absence of problems, patients should be fit for discharge within 24 hours. They should be given instructions to telephone the unit or their general practitioner and to return to the hospital if they are not making satisfactory progress.

Nausea

About half of patients experience some degree of nausea after laparoscopic surgery and rarely this is severe. It usually responds to an antiemetic, such as ondansetron, and settles within 12–24 hours. It is made worse by opiate analgesics and these should be avoided.

Shoulder tip pain

The patient should be warned about this preoperatively and told that the pain is referred from the diaphragm and not due to a local problem in the shoulders. It can be at its worst 24 hours after the operation. It usually settles within 2–3 days and is relieved by simple analgesics, such as paracetamol.

Abdominal pain

Pain in one or other of the port site wounds is not uncommon and is worse if there is haematoma formation. It usually settles very rapidly. Increasing pain after 2–3 days may be a sign of infection and, with concomitant signs, antibiotic therapy is occasionally required. Occasionally, herniation through a port may account for localised pain and this can sometimes be due to a Richter's hernia, such that the patient exhibits no sign of intestinal obstruction. Successful laparoscopic surgery should not cause the patients increasing or undue pain. If there are any clinical concerns postoperatively due to worsening pain, tachycardia and or pyrexia, senior review with a view to imaging, or increasingly commonly relaparoscopy, should be considered.

Analgesia

A 100-mg diclofenac suppository may be given at the time of the operation. It is important that the patient provides separate consent for this if the suppository is to be administered preoperatively. Suppositories may be administered a further two or three times postoperatively for relief of more severe pain. Otherwise, 500–1000 mg of paracetamol 4-hourly usually suffices (orally or if more pain, intravenously). Opiate analgesics cause nausea and should be avoided unless the pain is very severe. In this case, suspect a postoperative complication (as above). The majority of patients require between one and four doses of 1 g of paracetamol postoperatively. Severe pain after routine laparoscopic cases, should warn the clinician that there may be an iatrogenic or surgical cause of this pain that may need further investigation with blood tests, imaging and even relaparoscopy.

Orogastric tube

An orogastric tube may be placed during the operation if the stomach is distended and obscuring the view. It is not necessary in all cases. It should be removed as soon as the operation is over and before the patient regains consciousness. This is more routinely used in bariatrics and oesophagogastric surgery, where a larger, 32F or 34F tube is used.

Oral fluids

There is no significant ileus after laparoscopic surgery, except in resectional procedures, such as colectomy or small bowel resection. Patients can start taking oral fluids as soon as they are conscious; they usually do so 4–6 hours after the end of the operation.

Oral feeding

Provided that the patient has an appetite, a light meal can be taken 4–6 hours after the operation. Some patients remain slightly nauseated at this stage, but almost all eat a normal breakfast on the morning after the operation.

Patients will require advice about what they can eat at home. They should be told that they can eat a normal diet but should avoid excess. It seems sensible to avoid high-fat meals for the first week, although there is no clear evidence that this is necessary.

Urinary catheter

If a urinary catheter has been placed in the bladder during the operation, it should be removed before the patient regains consciousness. The patient should be warned of the possibility and symptoms of postoperative cystitis and told to seek advice in the unlikely event of this occurring.

Drains

Some surgeons drain the abdomen at the end of laparoscopic cholecystectomy, although this is controversial. If a drain is placed to vent the remaining gas and peritoneal fluid, it should be removed within 1 hour of the operation. If it has been placed because of excessive hepatic bleeding or bile leakage it should be removed when that problem has resolved, usually after 12–24 hours. Continued blood loss from a drain is an indication for re-exploration of the abdomen (Summary box 7.4).

Summary box 7.4

Surgical principles

- Meticulous care in the creation of a pneumoperitoneum
- Controlled dissection of adhesions
- Adequate exposure of operative field
- Avoidance and control of bleeding
- Avoidance of organ injury
- Avoidance of diathermy damage
- Vigilance in the postoperative period

DISCHARGE FROM HOSPITAL

Most surgeons discharge a significant proportion of their laparoscopic cholecystectomy patients on the day of surgery, but some are kept in overnight and discharged the following morning. Patients should not be discharged until they are seen to be comfortable, passed urine and eating and drinking satisfactorily. They should be told that if they develop abdominal pain or other

severe symptoms then they should return to the hospital or to their general practitioner. Even for more major cases, including procedures such as laparoscopic anterior resection, some units have demonstrated a safe and feasible protocol for a 23-hour stay.

Skin sutures

If non-absorbable sutures or skin staples have been used they can be removed from the port sites after 7 days.

Mobility and convalescence

Patients can get out of bed to go to the toilet as soon as they have recovered from the anaesthetic and they should be encouraged to do so. Such movements are remarkably pain free when compared with the mobility achieved after an open operation. Similarly, patients can cough actively and clear bronchial secretions, and this helps to diminish the incidence of chest infections. Many patients are able to walk out of hospital on the evening of their operation and almost all are fully mobile by the following morning. Thereafter, the postoperative recovery is variable. Some patients prefer to take things quietly for the first 2–3 days, interspersing increasing exercise with rest. After the third day, patients will have undertaken increasing amounts of activity. The average return to work is about 10 days.

THE PRINCIPLES OF COMMON LAPAROSCOPIC PROCEDURES

The principles of common laparoscopic procedures are described in the appropriate chapters:

- laparoscopic cholecystectomy (Chapter 63);
- laparoscopic inguinal hernia repair (Chapter 57);
- laparoscopic antireflux surgery (Chapter 59);
- laparoscopic appendicectomy (Chapter 67).
- laparoscopic bariatric surgery (Chapter 64)
- laparoscopic colectomy/anterior resection (Chapters 69 and 72)
- laparoscopic upper gastrointestinal (GI) surgery (Chapters 62, 63 and 64)

Other elective laparoscopic or minimally invasive procedures that are becoming more widely utilised in certain specialist centres include:

- colectomy;
- gastrectomy
- splenectomy;
- nephrectomy;
- adrenalectomy;
- prostatectomy;
- thyroid and parathyroid surgery;
- aortic aneurysm surgery;
- single-vessel coronary artery bypass surgery;
- video-assisted thorascopic surgery (VATS);
- laparoscopic hernia surgery (inguinal, femoral, paraumbilical, incisional).

Laparoscopy has also been used in certain emergency situations (in stable patients) in the hands of experienced laparoscopic surgeons. These may include diagnostic laparoscopy, repair of a perforated duodenal ulcer, laparoscopic appendicectomy, treatment of intestinal obstruction secondary to adhesions, strangulated

hernia repairs and, also, the laparoscopic evaluation of stable trauma patients.

Procedures that have been carried out using robotically assisted minimally invasive surgery include all of those listed above. Currently, robotic surgery still has certain disadvantages:

- increased cost;
- increased set up of the system and operating time;
- socioeconomic implications;
- significant risk of conversion to conventional techniques;
- prolonged learning curve;
- multiple repositioning of the arms can cause trauma;
- haemostasis;
- collision of the robotic arms in extreme positions.

Until these are overcome, by continued development of the technology and the drive of surgeons to progress in the field, robotically assisted surgery will not be commonplace. However, the potential for such systems is immense and continued research and clinical trials will pave the way for future generations of surgeons and patients alike.

FURTHER DEVELOPMENTS THAT HAVE MADE MINIMALLY INVASIVE SURGERY EVEN LESS INVASIVE

Single incision laparoscopic surgery

Laparoscopy has reduced the trauma from surgery compared to open techniques and is now used routinely for benign and oncological surgery in many centres. However, there is continued work on how to reduce the trauma and scarring from the incisions used in laparoscopic surgery as multiple port sites are needed for most procedures. Natural orifice transluminal endoscopic surgery (NOTES) (see below) addresses this but at present, the safety of the transgastric route is not sufficient for the routine use of this approach to surgery. Advanced laparoscopists have therefore turned to focussing on the single incision for open entry via the umbilicus as an alternative. Single incision laparoscopic surgery (SILS) is a technique adopted by some surgeons to insert all the instrumentation via a single incision, through a multiple channel port via the umbilicus to carry out the procedure. The benefit is that only one incision, through a natural scar (the umbilicus), is made therefore these procedures are virtually 'scarless'. Second, less port sites around the abdomen have the potential for less pain, less risk of port site bleeding and reduced incidence of port site hernia. This technique has many other synonyms, including laparoendoscopic single site surgery (LESS) and single port access (SPA) surgery among many others. It does require specially manufactured multichannel ports and often roticulating instruments. There has been an explosion of activity in SILS procedures in the last few years and in some units, laparoscopic cholecystectomies and hernias are routinely started as SILS cases. However, the clinical benefit for this technique which has a difficult and steep learning curve is still awaited from randomised trials being carried out internationally. Non-randomised data have shown understandably better cosmetic outcomes and even less pain in the immediate postoperative period, however, this needs to be further corroborated with randomised data.

Natural orifice transluminal endoscopic surgery

This technique, whereby surgeons enter the peritoneal cavity via endoscopic puncture of a hollow viscus, has been much publicised in recent years. Transvaginal NOTES cholecystectomies have been performed in humans successfully, but most still use hybrid procedures for safety reasons with direct laparoscopic guidance. The closure of the visceral puncture site is the issue that really has prevented widespread uptake of this technique, as transgastric and transcolonic closure of peritoneal entry sites in a routinely safe way is not yet perfected. Also, the equipment needed has significant cost and requires a large number of practitioners in the team at present. Nevertheless, it has much promise to be a technique for truly scarless surgery in the future and much research is being carried out on this field which is less widely adopted at present compared to SILS.

THE FUTURE

Although there is no doubt that minimal access surgery has changed the practice of surgeons, it has not changed the nature of disease. The basic principles of good surgery still apply, including appropriate case selection, excellent exposure, adequate retraction and a high level of technical expertise. If a procedure makes no sense with conventional access, it will make no sense with a laparoscopic approach. Laparoscopic and robotic surgery training is key to allow the specialty to progress. The pioneers of yesterday have to teach the surgeons of tomorrow not only the technical and dextrous skills required, but also the decision-making and innovative skills necessary for the field to continue to evolve. Training is often perceived as difficult, as trainers have less control over the trainees at the time of surgery and case loads may be smaller, especially in centres where laparoscopic and robotic procedures are not common. However, trainees now rightly expect exposure to these procedures and training systems should be adaptable for international exposure so that these techniques can be disseminated worldwide.

Improvements in instrumentation, the continued progress of robotic surgery and the development of structured training programmes are the key to the future of minimal access surgery. The use of robots in surgery has increased dramatically in the last decade. Indeed, robots are now available not only for assisting in surgery, but also for aiding in the perioperative management of surgical patients. The remote presence systems (In Touch Health, Santa Barbara, CA, USA; Figures 7.11 and 7.12) allow clinicians to assess patients in real time and interact with them while they are not on site or even if in a different continent. Continued advances in related technologies, such as computer science, will allow the incorporation of augmented reality systems alongside robotic systems to enhance surgical precision in image-guided surgery. Endoluminal robotic surgery is in its infancy, but systems are being developed that will enable navigation within the colon to allow surgery on lesions in spaces that are accessible from the outside without an exterior incision being made. The advent of nanotechnology will also bring about much change in surgery. Miniaturisation will be possible, potentially allowing surgery at a cellular level to be carried out.

At present, work has already started on single-port laparoscopy (see above under Single incision laparoscopic surgery),

Figure 7.11 Remote presence robot (courtesy of the Department of Biosurgery and Surgical Technology, Imperial College, London).

Figure 7.12 Remote presence console (courtesy of the Department of Biosurgery and Surgical Technology, Imperial College, London).

in which a single port may act as a camera and have unfolding instruments open up once they are inside the peritoneum to perform the surgery, therefore reducing the number of port sites needed. Extensive research is also being carried out in the field of NOTES. Minimising the potential contamination of the peritoneum and the ability to carry out a safe closure of the peritoneal entry site are the main technical challenges of this type of minimally invasive and essentially 'scarless' or 'incisionless' surgery.

It is certain that there is much that is new in minimal access surgery. Only time will tell how much of what is new is truly better.

The cleaner and gentler the act of operation, the less the patient suffers, the smoother and quicker his convalescence, the more exquisite his healed wound.

Principles of paediatric surgery

LEARNING OBJECTIVES

To recognize and learn:

- The important differences between adults and children which have clinical implications
- The principles of trauma management in children
- How to safely prescribe perioperative fluids in children
- How to avoid the pitfalls that lead to a missed or delayed diagnosis for common emergency conditions
- A collection of congenital malformations managed by neonatal surgeons that may present later to general surgeons
- The common safeguarding issues in children and know how to proceed if abuse is suspected

INTRODUCTION

Premature and term neonates differ in their anatomy, physiology, neurology, psychology, pathology and pharmacology, just as infants differ from school-age children and adolescents from adults (Table 8.1). These differences underpin the principles of paediatric surgery. A few examples appear in Table 8.2 and in Figure 8.1, but are not exhaustive.

A knowledge of teratology is fundamental to paediatric surgery, but since some anomalies first present to adult services (e.g. duplications, malrotation) this knowledge can occasionally pay dividends to surgeons dealing with adults. Adult surgical services also need to cater for the transitional needs of those graduating to adulthood, sometimes after complex paediatric surgical attention. Generally, children escape the comorbidities of degenerative diseases, but lifestyle problems, such as obesity, drug abuse and sexually transmitted diseases are no longer rare.

We start with three important areas: (1) thermoregulation, (2) airway and (3) fluid management, and then outline trauma, some common problems in older children, a collection of neonatal surgical conditions, oncology and safeguarding children.

Table 8.1 Common terms.

Preterm	<37 completed weeks' gestation
Full term	Between 37 and 42 completed weeks of gestation
Neonate	Newborn baby up to 28 days of age
Infant	Up to 1 year of age
Child	All ages up to 16 years, but often divided into preschool child (usually <5 years), child and adolescent (puberty up to 16 years)

Table 8.2 Some example differences between adults and children.

Facts	<p>Infants and small children have a wide abdomen, a broad costal margin and a shallow pelvis</p> <p>The edge of the liver comes below the costal margin and the bladder is largely intra-abdominal</p> <p>The ribs are more horizontal and are flexible</p> <p>The umbilicus is relatively low lying</p>
Implications	<p>Transverse supraumbilical incisions give greater access than vertical midline ones for open surgery</p> <p>Trauma (including surgical access) can easily damage the liver or bladder</p> <p>The geometry of the ribs means that ventilation requires greater diaphragmatic movement. Their flexibility means that rib fractures are rare and often a sign of abuse</p> <p>A stoma in the lower abdomen of a neonate must be carefully sited for its bag not to interfere with the umbilicus</p>

MAINTAINING TEMPERATURE

In comparison with older children, infants have less subcutaneous fat, immature vasomotor control, greater heat loss from pulmonary evaporation, and their surface area to weight ratio is higher. These need to be considered when managing sick children in the accident and emergency department, anaesthetic room or operating theatre. These environments must be warm

Figure 8.1 Topographical differences in the abdomen.

and the infant's head (20 per cent of surface area compared with 9 per cent in an adult) should be insulated. Infusions are warmed, and respiratory gases both warmed and humidified. The core temperature is monitored and safe direct warming is needed for lengthy operations.

AIRWAY

There are a number of differences in the airway and these have clinical implications (see Figure 8.2). The infant's large head and short neck predispose to flexion. The large tongue can obstruct the airway when unconscious and impede the airway and laryngoscopy. The epiglottis projects posteriorly and the larynx is high, favouring a straight-bladed laryngoscope in those under one year of age. Uncuffed tubes are preferred as the cricoid ring is the narrowest area (compared with the larynx in an adult) and this is covered in loose epithelium that is easily irritated and damage can result in subglottic stenosis.

PERIOPERATIVE FLUIDS IN CHILDREN

Before prescribing fluids (or drugs), the child's weight must be known, their vital signs and their fluid and electrolyte requirements should be considered in relation to normal values and ranges (see Table 8.3). Dehydration is difficult to assess: moderate dehydration (5 per cent loss of total body water) may manifest in poor urine output, dry mouth, and sunken eyes and fontanelle; severe dehydration (>10 per cent) in decreased skin turgor, drowsiness, tachycardia and poor capillary refill (>2 s) and signs of hypovolaemia.

Children develop hyponatraemic encephalopathy at higher sodium levels than adults because they have a higher brain–skull ratio. A few children have had symptomatic hyponatraemic encephalopathy attributable to poor prescription and monitoring of fluids, some have died and others have permanent neurological disability. Problems have arisen when (1) hypotonic maintenance fluids (e.g. 0.18 per cent saline), have been inappropriately given to resuscitate or replace losses or (2) maintenance fluids have been given in excess (three to five times that required).

Figure 8.2 Summary of upper airway anatomy in an infant.

Table 8.3 Basic paediatric data.

(a) Weight

Age	Weight (kg)
Term neonate	3.5
1 year	10
5 years	20
10 years	30

(b) Vital signs

Age (years)	Heart rate (bpm)	Systolic blood pressure (mmHg)	Respiratory rate (b/min)
<1	110–160	70–90	30–40
2–5	90–140	80–100	25–30
5–12	80–120	90–110	20–25

(c) Maintenance fluid requirements

Weight	Daily fluid requirement (mL/kg/day)	(mL/kg/hour)
Neonate	120–150	5
Older child:		
First 10 kg	100	4
Second 10 kg	50	2
Each subsequent kg	20	1

(d) Maintenance electrolyte requirements

Weight	Sodium (mmol/kg/day)	Potassium (mmol/kg/day)	Energy (kcal/kg/day)
<10 kg	2–4	1.5–2.5	110
>10 kg	1–2	0.5–1.0	40–75

Approximate guide: weight (kg) = $2 \times (\text{age in years} + 4)$, or use a Broselow tape which estimates the weight from the height.
 Systolic blood pressure = $80 + (\text{age in years} \times 2)$ mmHg.
 Circulating blood volume = 80 mL/kg (90 mL/kg in infants).

Tonicity and osmolality

The term 'isotonic' is now considered in relation to the tonicity of the electrolyte components of fluids. Thus, isosmolar fluids such as 0.18 per cent saline with 4 per cent glucose and hyperosmolar fluids such as 0.45 per cent saline with 5 per cent glucose are now considered 'hypotonic' because the glucose is ignored. The National Patient Safety Agency (NPSA) in 2007 instructed that all stocks of 0.18 per cent saline with 4 per cent glucose be removed from non-specialised areas to reduce the risks of hyponatraemia from inappropriate prescription.

Prescribing intravenous fluids

The four reasons for prescribing fluids are detailed in Summary box 8.1. The body's response to stress is to hold on to water and this promotes hyponatraemia. The stresses that drive the non-osmotic retention of water include trauma, head injury, chest infections and the postoperative state. Restricting maintenance fluids to 70 per cent is thus appropriate for 24 hours after major

surgery. The liberation of the fluid rate is guided by the results of daily electrolyte levels. Urine output will often be reduced after major surgery, but a common response to this can be to inappropriately increase maintenance fluid. A bolus of fluid is only appropriate if hypovolaemia is evident and needs correction.

In the surgical setting, **hyponatraemia** is usually a consequence of too much free water and **not** insufficient sodium. If mild and asymptomatic (e.g. 130 mmol/L) then fluid restriction is appropriate. If symptomatic with headache, lethargy or seizures and the Na level is <125 mmol/L, a rapid infusion of 4 per cent hypertonic saline is needed and paediatric intensive care unit (PICU) admission.

HISTORY AND EXAMINATION

Time, patience and a genuine interest will help to establish a good rapport with the child and their parents or carers. An opportunistic rather than a systematic approach to the history and examination may be needed, but appropriate areas must be covered. Do not forget to explore perinatal problems and the family and social background. Children should be told what to expect from an examination, investigation or surgical procedure in terms that they can understand. Fear, anxiety and pain can be reduced by involving the parents and by looking after the child in an appropriate environment. General health concerns are best discussed with a paediatrician.

OPERATIVE SURGERY

A well-prepared patient who has not been excessively starved (Summary box 8.2), with appropriate consent, is anaesthetised in a child-friendly anaesthetic room. Surgery demands meticulous and gentle technique, strict haemostasis, fine suture materials and often magnification aids. Basic principles apply: maintaining well-vascularised tissues, avoiding tension, minimising tissue necrosis and contamination. The intestine can be anastomosed with single-layer interrupted extramucosal sutures. Abdominal wounds are closed with absorbable sutures using a layered or a mass closure. Wound dehiscence is rare and usually the result of poor technique. Clean skin incisions are best closed with absorbable subcuticular sutures. Endoscopic minimally invasive approaches can be used at all ages to achieve the same advantages as in adults, but instruments and insufflation pressures must be tailored to the size of the child. Postoperatively, children recover swiftly. Analgesia must be adequate and appropriate, recognising the potential for respiratory depression with opioids. Appropriately trained staff monitor the airway, vital signs, oxygen saturation, fluid balance, temperature, pain control and glucose levels during recovery (Summary box 8.3).

Summary box 8.1

Fluids in children

Fluids are given intravenously for four reasons:

- Circulatory support in resuscitating vascular collapse.
(Given as a bolus of 10 or 20 mL/kg over periods up to 20 minutes with close monitoring of the response. Can be repeated up to 40 mL/kg, then seek urgent help)
 - 0.9 per cent saline
 - Blood
 - 4.5 per cent albumin
 - Colloid
- Replacement of previous fluid and electrolyte deficits. (Given over a longer period up to 48 hours with clinical and biochemical review)
 - 0.9 per cent saline + 0.15 per cent KCl
 - Hartmann's solution
- Replacement of ongoing losses (or a fluid tailored to the losses, e.g. 4.5 per cent albumin if protein loss is great. Replace losses mL for mL)
 - 0.9 per cent saline + 0.15 per cent KCl
 - Hartmann's solution
- Maintenance outside neonatal period (hypotonic 0.18 per cent saline should not be used outside the neonatal period)
 - 0.45 per cent saline + 0.15 per cent KCl in 2.5–5 per cent glucose
 - Hartmann's ± glucose
 - 0.9 per cent saline + 0.15 per cent KCl ± glucose
- Maintenance in the neonate
 - In term neonates in the first 48 hours of life, 10 per cent glucose at 60 mL/kg per day
 - Sodium 0.18 per cent and potassium 0.15 per cent are added on day 2
 - From day 3, around 4–5 mL/kg per hour or 100–120 mL/kg per day
 - Preterm babies or those <2 kg may require 180 mL/kg/day of fluid
 - Consider impaired gluconeogenesis: monitor and keep glucose above 2.6 mmol/L

Summary box 8.2

Starvation instructions

- Two hours for clear fluids
- Four hours for breast milk
- Six hours for solids

Summary box 8.3**Surgical technique in children**

- Gentle tissue handling
- Abdominal incisions can be closed with absorbable sutures
- Bowel can be anastomosed with interrupted single-layer extramucosal sutures
- Skin can be closed with absorbable subcuticular sutures

Stomas are necessary in some children. A gastrostomy may be required for nutritional support, particularly in the neurologically disabled child. Temporary intestinal stomas are used in the management of anorectal malformations, necrotising enterocolitis and Hirschsprung's disease. Infants with a proximal stoma and high losses frequently require salt or bicarbonate supplements to avoid deficits, which can cause poor weight gain and acidosis.

Surgeons who operate on children should consider the long-term outcomes of surgical disease and its treatment during maturation and adult life. For example, ileal resection in the neonate may later be complicated by vitamin B12 deficiency, malabsorption of fat-soluble vitamins, gallstones, renal oxalate stones and perianastomotic ulceration. Long-term concerns include the impact on continence, fertility, sexual activity, psychosocial adaptation, and the potential risk of late malignancy (e.g. undescended testis, choledochal cyst, duplication cysts).

PAEDIATRIC TRAUMA

Trauma remains a leading cause of death in children and adolescents worldwide. Many of these deaths are avoidable if prompt treatment is given well. Surgeons should attend the Advanced Trauma Life Support (ATLS) programme which covers trauma in children. Some of the important differences for children follow:

- Avoid overextension of the neck which can obstruct the airway.
- Use a Broselow tape if the weight is not known.
- Blood pressure is often normal until >25 per cent of the circulating blood volume is lost.
- Cardiorespiratory arrest is usually due to hypoxia and not vascular disease.
- Diagnostic peritoneal lavage is obsolete in children.

Resuscitation

For information related to fluids, see Summary box 8.1. High-flow oxygen is required if there is cardiorespiratory compromise, and endotracheal intubation and ventilation are required if oxygenation is inadequate or to control a flail chest or in children with a serious head injury (Glasgow Coma Score ≤ 8). Seriously injured children require two large peripheral intravenous canulae. The long saphenous at the ankle, femoral, external jugular and, in babies, scalp veins can be used. Central venous access should only be attempted by an expert. Intraosseous infusion

The **Glasgow Coma Score** was introduced in 1977 by William Bryan Jennet, Professor of Neurosurgery, and Graham Michael Teasdale, a neurosurgeon at the University Department of Neurosurgery at the Institute of Neurological Sciences, The Southern General Hospital, Glasgow, UK. Professor Teasdale was later knighted and became President of the Royal College of Physicians and Surgeons of Glasgow.

Figure 8.3 The intraosseous needle is inserted into the medullary cavity of the proximal tibia about 1–3 cm below the tibial tuberosity.

however, is straightforward and particularly useful in children (Figure 8.3).

A major spinal cord injury can be present in a child without radiographic abnormalities. After major trauma, a cervical spine injury should be assumed and the neck immobilised until cross-sectional imaging 'clears' the spine. Other considerations include intravenous analgesia and, in the unconscious or ventilated child or those with major abdominal injuries, a nasogastric tube (orogastric if suspicion of a basal skull fracture) and a urethral catheter (if no evidence of a urethral injury).

Secondary survey and emergency management

Chest trauma

Children have elastic ribs that rarely fracture but deformation causes lung contusions. A major thoracic injury may exist despite a normal chest radiograph. The airway is secured, oxygen is given and hypovolaemia is corrected. A tension pneumothorax should be suspected clinically before the chest x-ray is requested and immediate needle thoracocentesis (second intercostal space, mid-clavicular line) performed. A chest drain is then placed (fifth intercostal space, mid-axillary line). Massive haemothorax needs a chest drain. Cardiac tamponade may follow blunt or penetrating injury and requires emergency needle pericardiocentesis. Diaphragmatic rupture after blunt abdominal trauma is detected by chest radiography or computed tomography (CT) scan; surgical repair is undertaken once the patient is stable (Figure 8.4).

Abdomen

Blunt trauma is more common than penetrating trauma. The liver and spleen are more vulnerable in children being less well protected by the rib cage. The abdomen is inspected for patterned bruising from seatbelts (Figure 8.5) or tyres. Compression will have been against the rigid skeleton. Intra-abdominal or intrathoracic bleeding should be considered promptly in the shocked child if external bleeding has not been profuse. Plasma amylase levels may be normal despite pancreatic injury (Figure 8.6).

Figure 8.4 Traumatic diaphragmatic rupture.

Figure 8.5 Bruises from a lap belt.

Imaging

Focused assessment with sonography for trauma (FAST) looks for fluid in the perihepatic and hepatorenal space, the perisplenic area, the pelvis and the pericardium. It has a role in children but it does not detect solid organ injuries nor replace CT. In the haemodynamically stable child, a CT scan with intravenous contrast is required (Figure 8.7).

Bowel perforation or deep penetrating trauma require a laparoscopy or laparotomy. Isolated blunt splenic and/or liver injuries identified on a CT scan can be safely and effectively managed non-operatively (Summary box 8.4) in the majority of children, so avoiding surgery and the long-term risks of splenectomy.

Summary box 8.4

Requirements for successful non-operative management of isolated blunt liver or spleen trauma

- Haemodynamic stability after resuscitation with no more than 60 mL/kg of fluid
- A good-quality computed tomographic scan
- No evidence of hollow visceral injury
- Close monitoring and the immediate availability of surgical expertise and facilities

Figure 8.6 Abdominal computed tomographic scan showing a transection through the neck of the pancreas (arrow) from a bicycle handlebar injury.

Ongoing intra-abdominal bleeding requires a laparotomy, though angiography and arterial embolisation can be useful in some. Bile leaks are uncommon and can usually be managed by an interventional radiological technique. Uncomplicated unoperated cases of liver/spleen trauma can be discharged after 5–7 days but activity is restricted for 3–6 weeks and contact sports avoided for between two and three months. Blunt renal trauma can be managed conservatively, but an acutely non-functioning kidney following abdominal trauma may need urgent exploration with a view to revascularisation.

Summary box 8.5

Paediatric trauma

- Use Advanced Trauma Life Support (ATLS) principles
- Overextension of the neck will compromise the airway
- Cervical spine injury can be present without radiographic signs
- Intraosseous vascular access is helpful in small children
- Lung contusion can occur without rib fractures
- Patterned skin bruising suggests underlying organ injury
- In a stable child, abdominal injuries are best assessed by computed tomography
- Isolated liver or splenic injury can usually be managed non-operatively

Patterns of injury

- Lap belts: the small intestine or lumbar spine.
- Bicycle handlebars: pancreatic, duodenal or liver trauma (Figure 8.6).
- Straddle injuries: the urethra and pelvis.
- Run-over injuries: severe crushing of the chest, and/or abdomen and/or pelvis.

The main principles for managing trauma in children appear in Summary box 8.5.

Figure 8.7 Abdominal computed tomographic scan after intravenous contrast in an 11-year-old boy showing a ruptured spleen (successfully managed non-operatively).

COMMON PAEDIATRIC SURGICAL CONDITIONS

Inguinoscrotal disorders

Most genital abnormalities in boys are the result of abnormal development. The testis develops from the urogenital ridge on the posterior abdominal wall. Gonadal induction to form a testis is regulated by genes on the Y chromosome. In the abdominal descent, the testis migrates towards the internal ring, guided by mesenchymal tissue (gubernaculum). Descent into the scrotum is mediated by testosterone from the fetal testis. A tongue of peritoneum precedes the migrating testis through the inguinal canal; this is the processus vaginalis. This peritoneal pouch normally becomes obliterated after birth, but failure to do so leads to the development of an inguinal hernia or hydrocoele (Figure 8.8).

Inguinal hernias

Inguinal hernias in children are almost always indirect and due to a patent processus vaginalis. They are more frequent in boys, especially if premature. An inguinal hernia will develop in at least one in 50 boys and about 15 per cent are bilateral. Rarely, bilateral inguinal hernias in a phenotypic girl may be the pre-

Figure 8.8 (a) Inguinal hernia and (b) hydrocoele in children are the result of incomplete obliteration of the processus vaginalis.

Figure 8.9 A left inguinal swelling. Clinical examination is needed to confidently distinguish a hydrocoele from an inguinal hernia.

sending feature of androgen insensitivity syndrome (testicular feminisation) and the hernia sac may then contain a testis.

An inguinal hernia typically causes an intermittent swelling in the groin or scrotum on crying or straining (Figure 8.9). Unless an inguinal swelling is observed, the diagnosis relies on the history and the presence of palpable thickening of the spermatic cord (or round ligament in girls). Some inguinal hernias present as a firm, tender, irreducible lump in the groin or scrotum because of incarceration at the external ring. The infant may be irritable and vomit. Most incarcerated hernias in children can be successfully reduced by sustained gentle compression ('taxis') aided by cautious analgesia. Repair is delayed for 24 hours to let the oedema settle. If truly irreducible, emergency surgery is required because of the risk of vascular compromise to the bowel, ovary or testis.

Inguinal herniotomy is performed via an inguinal skin crease incision, opening Scarpa's fascia and then the external oblique. The cremaster is cut and, through an initially small opening, the cord grasped and gently delivered. The vas and vessels are separated from the sac which is then divided and proximally ligated. Outside the neonatal period, inguinal herniotomy is treated as day-case surgery (Summary box 8.6).

Summary box 8.6

Inguinal hernias

- More common in premature boys
- 15 per cent bilateral
- Indirect with a patent processus vaginalis
- Groin lump that appears on straining or crying
- Incarcerated inguinal hernias can usually be reduced with gentle pressure
- In infants, they can transilluminate like a hydrocoele making the test redundant when the distinction is difficult
- If reduction is impossible, emergency surgery is needed
- Infants need repair promptly to prevent the risk of strangulation
- The hernial sac is isolated, ligated and divided

Hydrocoeles

A patent processus vaginalis may allow only peritoneal fluid to track down around the testis to form a hydrocoele. Hydrocoeles are unilateral or bilateral, asymptomatic, non-tender scrotal swellings. They may be tense or lax, but typically transilluminate. The majority resolve spontaneously as the processus continues to obliterate, but surgical ligation is recommended in boys older than three years of age.

Undescended testes are palpable or impalpable

At birth, about 4 per cent of full-term boys have unilateral or bilateral undescended testes, but by one year of age it is <1 per cent and it changes little thereafter. The incidence is higher in preterm infants because the testis descends through the inguinal canal during the third trimester. A normal testis reaches the base of the scrotum with a good length of cord above it. Testes cannot be palpated in the inguinal canal, but can be milked from there into the superficial pouch (**palpable undescended testis**) or in to the scrotum with a good length of cord (normal). A **retractile testis** can be manipulated into the base of the scrotum without tension, but is pulled up by the cremaster muscle. With time, retractile testes reside permanently in the scrotum; however, follow up is advisable as, rarely, the testis ascends into the inguinal canal. The **ascending testis** needs an orchidopexy. An **ectopic testis** lies outside its normal line of descent, often in the perineum (Summary box 8.7).

Summary box 8.7

The undescended testis

- A retractile testis reaches the base of the scrotum, but retracts
- An undescended testis may be palpable or impalpable
- An ectopic testis lies outside the normal line of descent
- Palpable undescended testes undergo a single stage orchidopexy
- Impalpable undescended testes usually require a two stage orchidopexy
- Orchidopexy around one year of age improves fertility and may reduce the risk of malignancy

A palpable undescended testis should undergo a day-case orchidopexy around one year of age. The testis is mobilised through an inguinal incision, preserving the vas deferens and testicular vessels. The associated patent processus vaginalis is ligated and divided, and the testis is placed in a subdartos scrotal pouch.

Impalpable undescended testes are either absent or located in the abdomen or inguinal canal. There is no benefit from imaging and these are best managed with a laparoscopy (Figure 8.10) and usually a staged approach.

The benefits of orchidopexy include:

- **Fertility.** To optimise spermatogenesis, the testis needs to be in the scrotum below body temperature at a young age. Orchidopexy around one year of age is currently recommended. Fertility after orchidopexy for a unilateral

Figure 8.10 Laparoscopic view of a right-sided intra-abdominal testis visible at the internal ring. Vas (single arrow) and testicular vessels (double arrow).

undescended testis is near normal. Men with a history of bilateral intra-abdominal testes are often infertile.

- **Malignancy.** Undescended testes are histologically abnormal and at an increased risk of malignancy. The greatest risk is for bilateral intra-abdominal testes. Early orchidopexy for a unilateral undescended testis may reduce the risk, but this is not proven.
- **Cosmetic and psychological.** In an older boy, a prosthetic testis can be inserted to replace an absent one.

The acute scrotum

Testicular torsion is most common in adolescents, but may occur at any age, including in the perinatal period. The pain is not always scrotal and may be felt in the groin or lower abdomen. Oedema and erythema of the scrotal skin can be absent. Sometimes there is a history of previous transient episodes. Torsion of the testis must be relieved within 6–8 hours of the onset of symptoms for there to be a good chance of testicular salvage. At operation, viability of the testis is assessed after derotation. If salvageable, three-point fixation of both testes with non-absorbable sutures is performed. Expert assessment of testicular blood flow by colour Doppler ultrasound may help in the differential diagnosis, but the scrotum must be explored urgently if torsion cannot be excluded.

Torsion of a testicular or epididymal appendage characteristically affects boys just before puberty (Figure 8.11), possibly because of enlargement of the hydatid in response to gonadotrophins. A hydatid of Morgagni is an embryological remnant found on the upper pole of the testis or epididymis. The pain often increases over a day or two. Occasionally, the tortured hydatid can be felt or seen (blue dot sign). Excision of the appendage leads to rapid resolution of symptoms. Viral or bacterial **epididymo-orchitis** may cause an acute scrotum in infants and toddlers, but the diagnosis is often only made after scrotal exploration. Other conditions that rarely cause acute scrotal symptoms and signs include idiopathic scrotal oedema (typically painless, erythematous scrotal swelling in a young boy extending from the scrotum into the groin and towards the anus), an

Figure 8.11 Acute scrotal pathology at different ages.

incarcerated inguinal hernia, vasculitis or a scrotal haematoma (Summary box 8.8).

Summary box 8.8

Diagnosis and treatment of the acute scrotum

- Torsion of the testis must be assumed until proven otherwise
- Testicular torsion can present with acute inguinal or abdominal pain
- Urgent surgical exploration is crucial if testicular torsion cannot be excluded
- Torsion of a testicular appendage usually occurs just before puberty
- An incarcerated inguinal hernia must be considered in the differential diagnosis

The penis

Hypospadias

In hypospadias, seen in 1:300 boys, the urethra opens proximally and ventrally. Most commonly, the opening is just proximal to the glans, but it can open on the penile shaft or onto the perineum. It is attributed to failure of complete urethral tubularisation in the fetus. The foreskin is deficient ventrally and there is a variable degree of chordee (a ventral curvature of the penis most apparent on erection) (Figure 8.12). Glanular hypospadias needs correction for cosmetic reasons but more proximal anomalies interfere with micturition and erection. In a newborn with severe hypospadias and bilateral undescended testes, disorders of sexual development (DSD) should be considered. A distal hypospadias is usually repaired before two years of age in one or two stages. Proximal varieties require complex staged procedures. Surgery aims to achieve a terminal urethral meatus so that the boy can stand to micturate with a normal stream, a straight erection and a penis that looks normal. Ritual circumcision is contraindicated in infants with hypospadias because the foreskin is often required for the reconstruction.

The foreskin and circumcision

At birth, the foreskin is adherent to the glans penis. These adhesions separate spontaneously with time, allowing the foreskin to become retractile. At one year of age, about 50 per cent of boys have a non-retractile foreskin. By four years, this has declined

Figure 8.12 Hypospadias: note the hooded foreskin and the ventral meatus.

to 10 per cent and by 16 years to just 1 per cent. Ballooning of the normal non-retractile foreskin on micturition brings many young boys to doctors and explanation and reassurance are required, but no operation. Gentle retraction of the foreskin at bath times helps to maintain hygiene, but forcible retraction should never be attempted. The presence of preputial adhesions, when the foreskin remains partially adherent to the glans, is normal and resolves spontaneously.

Circumcision has been an important tradition in Jewish, Muslim and other cultures. Proponents observe that circumcision reduces the incidence of urinary tract infection in infant boys; however, circumcision is not without risk of significant morbidity. The medical indications for circumcision are:

- **Phimosis.** This term is often wrongly applied to describe a normal, non-retractile foreskin. True phimosis is seen as a whitish scarring of the foreskin and is rare before five years of age (Figure 8.13). It is caused by a localised skin disease known as balanitis xerotica obliterans (BXO), which also affects the glans penis and can cause urethral meatal stenosis.
- **Recurrent balanoposthitis.** A single episode of inflammation of the foreskin, sometimes with a purulent discharge, is not uncommon and usually resolves spontaneously; antibiotics are sometimes needed. Recurrent attacks are unusual but may be an indication for circumcision.
- **Recurrent urinary tract infection.** Circumcision is occasionally justified in boys with an abnormal upper urinary tract anomaly and recurrent urinary infection. It may also help boys with spina bifida who need to perform clean intermittent urethral catheterisation.

An emerging but controversial indication for circumcision is in the prevention of sexually acquired human immunodeficiency virus (HIV) infection in communities where this is common; large clinical trials have shown that circumcision reduces the risk of HIV transmission.

Figure 8.13 True phimosis from balanitis xerotica obliterans.

Circumcision for medical reasons is best performed under general anaesthesia. A long-acting local anaesthetic regional block can be given to reduce postoperative pain. Circumcision is not a trivial operation; bleeding and infection are well-recognised complications and more serious hazards, such as injury to the glans, may occur if the procedure is not carried out well (Summary box 8.9).

Summary box 8.9

Circumcision

- Medical indications are balanitis xerotica obliterans and recurrent balanoposthitis, paraphimosis, scarring from trauma
- Circumcision is not indicated for an otherwise healthy non-retractile foreskin
- Complications include bleeding, poor cosmesis (too much or too little skin removed) and trauma to the glans or urethra

Midline hernias

In the embryo, the umbilical ring is a relatively large defect in the ventral abdominal wall transmitting several structures that connect the fetus to the placenta (Figure 8.14). An umbilical hernia is common and caused by incomplete closure of the umbilical ring; incarceration is very rare. Most umbilical hernias resolve spontaneously by four years of age. Supraumbilical hernias are through defects in the linea alba just above the umbilical ring and these do not close, but are still repaired at around four years of age. Epigastric hernias are defects higher still that allow a small amount of preperitoneal fat to prolapse. They are repaired if symptomatic.

Figure 8.14 Structures at the umbilicus.

Infantile hypertrophic pyloric stenosis

Infantile hypertrophic pyloric stenosis (IHPS) presents with non-bilious projectile vomiting between 2 and 8 weeks of age and is only rarely seen after 13 weeks. It is easily distinguished from many other serious causes of vomiting, such as infections, because the baby is particularly hungry. IHPS is a progressive condition and a detailed history helps distinguish it from the more common gastro-oesophageal reflux (GOR) which is commonly seen in infancy. In the UK, it affects 1:300 infants with a male to female ratio of 4:1. However, if a girl has IHPS her offspring have a high chance of developing it, suggesting a genetic predisposition.

The non-bilious nature is stressed here to contrast the condition with the **bilious vomiting** of the potentially life-threatening malrotation and volvulus seen occasionally in neonates.

IHPS can be diagnosed clinically. During a test feed, there is visible gastric peristalsis passing from left to right across the upper abdomen and in a relaxed baby the pyloric 'tumour' is palpable as an 'olive' in the right upper quadrant. The diagnosis can be confirmed by an ultrasound, which shows the thickened pyloric muscle. IHPS is readily treated by surgery but the infant must be adequately rehydrated and the hypochloreaemic-hypokalaemic alkalosis corrected; this may take 48 hours. In most babies, the dehydration and alkalosis can be corrected by giving 150–180 mL/kg per day of 0.45 per cent saline with 0.15 per cent KCl in 5 per cent glucose. Oral feeding is discontinued and the stomach emptied with an 8–10 Fr nasogastric tube; ongoing gastric losses should be replaced with normal saline containing potassium chloride.

Ramstedt's pyloromyotomy is performed through an incision around the umbilicus. The pyloric tumour is delivered by gentle traction on the stomach. A serosal incision is made and the tumour spread (Figure 8.15). The end result should be an intact bulging submucosa from duodenal fornix to gastric antrum.

Perforation of the duodenal fornix is uncommon and not serious provided that it is recognised and repaired immediately.

Postoperatively, intravenous fluids are continued until oral feeding is re-established within 24 hours. Occasionally, the baby has small vomits on the first few feeds but this resolves after 72 hours. If it persists, then an incomplete myotomy or GOR should be considered. Surgical complications include duodenal perforation, haemorrhage, wound infection and wound dehiscence – all are uncommon and avoidable. Pyloromyotomy has no significant long-term sequelae (Summary box 8.10).

Summary box 8.10

Infantile hypertrophic pyloric stenosis

- Most commonly affects boys aged 2–8 weeks
- Projectile vomiting after feeds
- Test feed or ultrasound to confirm the diagnosis
- Gastric peristalsis can be seen and an ‘olive’ felt
- Hypochloraemic metabolic alkalosis must be corrected before surgery
- Pyloromyotomy splits the hypertrophied muscle leaving the mucosa intact

Other common or serious causes of vomiting in infancy are shown in Table 8.4.

Gastro-oesophageal reflux is common and tends to resolve spontaneously with maturity. Persistent symptoms respond to thickened feeds and anti-reflux medication. Complications, such as failure to thrive or respiratory problems, demand further investigation and, in some cases, fundoplication.

Intussusception

Most intussusceptions (Figure 8.16) in children are seen from two months to two years of age. They are life-threatening. Intussusception typically causes a strangulating bowel obstruction, which can progress to gangrene and perforation. Intussusception is classified according to the site of the intussusceptum and intussusciens. In children, more than 80 per

Table 8.4 Vomiting in infancy.

Bile-stained	Neonate	Intestinal malrotation with volvulus Duodenal atresia/stenosis (Down syndrome, antenatal diagnosis) Jejunal/ileal atresia (often isolated anomalies) Hirschsprung’s disease Anorectal malformations Meconium ileus (cystic fibrosis) Necrotising enterocolitis (an acquired condition in the premature) Incarcerated inguinal hernia
	Older infant	Intestinal malrotation with volvulus Intussusception (often non-bilious initially) Incarcerated inguinal hernia
Non-bilious	Infantile hypertrophic pyloric stenosis	
	Gastro-oesophageal reflux	
	Feeding difficulties (technique/volume)	
	Non-specific marker of illness, e.g. infection (urinary tract infection, meningitis, gastroenteritis, respiratory, metabolic disorder, raised intracranial pressure, congenital adrenal hyperplasia)	

cent are ileocolic, beginning several centimetres proximal to the ileocaecal valve with their apex found in the ascending or transverse colon.

In the majority, the cause is hyperplasia of Peyer’s patches (lymphoid tissue), which may be secondary to a viral infection. In 10 per cent of children, intussusception is secondary to a pathological lead point, such as a Meckel’s diverticulum, enteric

Figure 8.15 Pyloromyotomy for infantile hypertrophic pyloric stenosis.

Figure 8.16 Ileocolic intussusception causing small bowel obstruction.

duplication cyst or even a small bowel lymphoma. Such cases are more likely in children over the age of two years and in those with recurrent intussusception.

Classically, a previously healthy infant presents with colicky pain and vomiting (milk, then bile). Between episodes, the child initially appears well. Later, they may pass a 'redcurrant jelly' stool. Clinical signs include dehydration, abdominal distension and a palpable sausage-shaped mass in the right upper quadrant. Rectal examination may reveal blood or rarely the apex of an intussusceptum (Summary box 8.11).

Summary box 8.11

Presentation of intussusception

- Bilious vomiting in an infant is a sign of intestinal obstruction until proved otherwise
- Intussusception classically presents with colicky pain and vomiting
- Intussusception should be considered in any infant with bloody stools
- Age range is between 2 and 24 months of age

A plain radiograph is rarely requested but if done it commonly shows signs of small bowel obstruction and a soft-tissue opacity. Diagnosis is confirmed on an abdominal ultrasound. After resuscitation with intravenous fluids, broad-spectrum antibiotics and nasogastric drainage, non-operative reduction is attempted using an air enema (Figure 8.17). Successful reduction is recognised if air flows into the small bowel, together

with later resolution of symptoms and signs. An air enema is contraindicated if there is peritonitis, perforation or shock. More than 70 per cent of intussusceptions can be reduced non-operatively. Strangulated bowel and pathological lead points are unlikely to reduce. Perforation of the colon during pneumatic reduction is a recognised hazard, but is rare. Recurrent intussusception occurs in up to 5 per cent of patients after non-operative reduction (Summary box 8.12).

If an operative reduction is needed, this is usually performed open. The intussusception is milked distally by gentle compression from its apex. Both the intussusceptum and the intussusciptens are inspected for areas of non-viability. An irreducible intussusception or one complicated by infarction or a pathological lead point requires resection and primary anastomosis.

Summary box 8.12

Management of intussusception

- Bowel infarction will result without treatment
- Most are ileocolic
- Diagnosis can be confirmed by ultrasound scan
- Fluid and electrolyte resuscitation is essential
- Most intussusceptions can be reduced non-operatively using an air enema
- If there are signs of peritonitis or perforation, then an emergency operation is needed

Figure 8.17 Air enema reduction of an intussusception (the arrows mark the soft tissue shadow of the intussusceptum).

Acute abdominal pain in children over three years of age

Between one-third and one-half of children admitted to hospital with acute abdominal pain have non-specific abdominal pain (NSAP). Another one-third have acute appendicitis. Relatively benign conditions, such as constipation and urinary tract infection (UTI), account for most of the remainder. A small proportion of children have more serious pathology.

History and examination

Time and patience are required to accurately evaluate the child with acute abdominal pain. The child may be frightened and the parents worried. Young children find it difficult to accurately describe or localise abdominal pain, but can often give a good history. The abdomen, genitalia, chest, throat and neck are examined. The abdomen may need reassessment after analgesia and a number of reviews. A gentle abdominal examination of the sleeping toddler, before removing their clothes, may reveal tenderness, guarding or a mass. Rectal examination is only performed if a pelvic appendicitis is suspected and should be by the surgeon whose decision will be altered by the findings. **Active observation** acknowledges that a definitive diagnosis is not always possible when the patient is first seen. The surgeon reassesses the child after a few hours whilst rehydrating with intravenous fluids or allowing clear fluids and simple analgesics. This approach reduces the need for investigations and can reduce the negative appendectomy rate to as low as 4 per cent (Summary box 8.13).

Summary box 8.13**Work up of children with acute abdominal pain**

- A careful history and examination and active observation are paramount
- Routine tests include full blood count (FBC), C-reactive protein (CRP), urine analysis, microscopy and culture
- Other tests may be helpful after a period of observation: abdominal ultrasound scan (can diagnose pelvic and urinary tract pathology, intussusception and other conditions)
- Occasionally helpful tests: a plain supine abdominal radiograph (particularly in the preschool child with pain and vomiting), computed tomography scan in complex patients
- Selective specific investigations: blood culture, stool culture, plasma amylase, diagnostic laparoscopy

Acute non-specific abdominal pain

The clinical features of NSAP are similar to acute appendicitis, but the pain is poorly localised, not aggravated by movement and rarely accompanied by guarding. The site and severity of maximum tenderness often vary during the course of repeated examinations. Symptoms are typically self-limiting within 48 hours. The aetiology of non-specific abdominal pain in children is obscure, but viral infections and transient intussusception account for some cases. Viral infections can cause reactive lymphadenopathy, fever and diffuse abdominal pain. In some children, recurrent acute abdominal pain can be organic or sometimes an expression of underlying psychosocial problems or abuse.

Acute appendicitis and its pitfalls

Classically, there is anorexia and a few episodes of vomiting with central abdominal pain which settles in the right iliac fossa. In early acute appendicitis, there is a fever of 37.3–38.4°C and localised tenderness. Finding persistent guarding in the right iliac fossa on repeated examination is the key to making the diagnosis and distinguishing it from NSAP which usually resolves over 24 to 48 hours. NSAP does not have persistent guarding. Acute appendicitis is a clinical diagnosis and investigations may help, but cannot replace regular expert clinical review. The pitfalls include wrongly making the diagnosis of gastroenteritis when there are loose stools or attributing pain on micturition and pyuria to a UTI. Both of these can occur when there is a pelvic appendicitis or a pelvic collection. Consider also referred pain from a possible right lower lobe pneumonia and remember that if antibiotics have been given the signs may be subdued and presentation can be delayed. The diagnosis can be difficult in those under five years of age. However, many patients under the age of five present with a perforated appendix, not because the diagnosis is made late but rather the omentum is less well developed and inflammation is not well contained. The treatment starts with resuscitation with intravenous fluids, analgesia and broad-spectrum antibiotics. Appendectomy can be performed laparoscopically or through a muscle-splitting right iliac fossa incision. An appendix mass in a child who is not obstructed may respond to conservative

management with antibiotics and an interval appendectomy can be considered 6 weeks later (Summary box 8.14).

Summary box 8.14**Acute appendicitis**

- Anorexia, vomiting, low-grade fever
- Tenderness and guarding in the right iliac fossa
- Exclude referred pain from right lower lobe pneumonia
- Take special care in the preschool child
- Surgery is the treatment of choice after resuscitation and antibiotics

Other causes of acute abdominal pain in children

- **Intestinal obstruction.** Consider intussusception, inguinal hernia, adhesions and secondary to a Meckel's diverticulum.
- **Constipation.** Often over-diagnosed as a cause of acute abdominal pain, particularly as the plain x-ray of a dehydrated ill child frequently shows faecal loading. Constipation is more often a cause of acute abdominal pain in a child who has been treated for Hirschsprung's disease or an anorectal malformation.
- **Urinary tract disorders.** Urinary tract infection is an uncommon cause of acute abdominal pain. Urinary symptoms, fever and vomiting tend to predominate. Urinalysis, microscopy and culture are useful, but a sterile pyuria may accompany acute appendicitis. Boys with pelviureteric junction obstruction can present with acute or recurrent abdominal pain and no urinary symptoms.
- **Gastroenteritis.** May cause colicky abdominal pain. Onset of pain before the diarrhoea and the presence of lower abdominal tenderness should raise the suspicion of appendicitis.
- **Tropical diseases.** Ascariasis, typhoid and amoebiasis can cause acute abdominal pain.

There are numerous rarer causes of acute abdominal pain in children including Henoch–Schönlein purpura, sickle cell disease, primary peritonitis, acute pancreatitis, biliary colic, testicular torsion, gynaecological pathology (e.g. ovarian cysts and tumours, pelvic inflammatory disease, haematometocolpos) and urinary stone disease (Summary box 8.15).

Summary box 8.15**Rare causes of acute abdominal pain in children**

- Obstruction from intussusception, adhesions, Meckel's diverticulum or an inguinal hernia
- Constipation
- Urinary tract disorders
- Gastroenteritis
- Ascariasis
- Typhoid

Urinary tract infection

Urinary tract infections in children may be due to a urinary tract abnormality which may carry a risk of developing renal scarring from ascending infection. Infection and obstruction

is particularly hazardous. Older children complain of dysuria and frequency, whereas infants present with vomiting, fever and/or poor feeding. Urine specimens from children are easily contaminated during collection and results must be interpreted with care. A proven infection is investigated by an ultrasound scan. Micturating cystography and radioisotope renography are helpful in excluding vesicoureteric reflux and renal scarring. Treatment aims to relieve symptoms, correct causes and prevent renal scarring. Vesicoureteric reflux may resolve spontaneously, some may need antibiotic prophylaxis or, in a very small number of cases, an endoscopic treatment or a reimplantation of the ureter.

Children with **neuropathic bladders** (e.g. spina bifida) are at risk of secondary upper renal tract complications. Management of these children must take into account their dexterity and motivation. An adequate capacity, low-pressure bladder can frequently be managed by clean intermittent catheterisation, but a high pressure bladder is hazardous and other strategies, such as bladder augmentation, may be necessary. Some of these children empty their bladder via a non-refluxing catheterisable channel fashioned from the appendix, the bowel or a redundant ureter interposed between the abdominal wall and bladder (Mitrofanoff).

Anorectal problems

Constipation

The passage of hard or infrequent stools is common in children in the West. Severe constipation may be secondary to an anal fissure, Hirschsprung's disease, an anorectal malformation or a neuropathic bowel. A detailed history and examination of the abdomen, anus and spine will identify most causes. Rectal examination and plain abdominal radiography may be helpful in severe cases. In the absence of specific underlying pathology, the child is best managed jointly with a paediatrician using a combination of diet, extra fluids, reward systems, laxatives and, in some cases, psychological intervention.

Rectal prolapse

Mucosal rectal prolapse can occur in toddlers and is exacerbated by straining or squatting on a potty. It is typically intermittent and frequently self-limiting. Rarely, it may be secondary to cystic fibrosis or spinal dysraphism. The differential diagnosis includes a prolapsing rectal polyp. Underlying factors such as constipation should be treated. Recurrent symptomatic prolapse usually responds to injection sclerotherapy. Strapping the buttocks is ineffective.

Rectal bleeding

Unlike in adults, malignancy is an exceptionally rare cause of rectal bleeding. In newborns, the life-threatening causes are malrotation and necrotising enterocolitis and in older infants and children, intussusception. The quantities of blood loss are small, but the conditions serious. Other causes include anal fissures, juvenile polyps (Figure 8.18) and certain gastroenteritides (e.g. *Campylobacter* infection).

The four-year-old patient who presents with an Hb of 4 gm/dL will most likely have bled profusely from an ulcer adjacent to a Meckel's diverticulum containing ectopic gastric mucosa (Figure 8.19). A technetium scan may confirm the presence of

Figure 8.18 Colonic juvenile polyp: these are typically pedunculated.

Figure 8.19 Meckel's diverticulum containing ectopic gastric mucosa.

ectopic gastric mucosa (Figure 8.20). A Meckel's diverticulum may also be complicated by an obstructing band between the diverticulum and the umbilicus, diverticulitis, intussusception, intestinal volvulus or perforation.

Swallowed or inhaled foreign bodies

Coins are the most frequently swallowed foreign bodies in children. Once beyond the cardia, they are usually passed in a few days. A plain radiograph of the abdomen, chest and neck should establish the site of radio-opaque objects. Oesophageal objects can be removed endoscopically under general anaesthesia. Button batteries must be removed within hours. If they remain in the oesophagus they can cause gastrointestinal perforation into the trachea. Batteries in the stomach are either removed urgently or followed very closely with repeat x-rays over a couple of days. The need to remove sharp objects depends on their size, the age of the child and their position in the gut. Ingested magnets can cause entero-enteric fistulae when they fix to one another in adjacent loops of bowel.

Inhaled foreign bodies cause sudden-onset coughing and stridor. If there is worsening dyspnoea or signs of hypoxia, then the infant should be given back blows in a head-down position. A Heimlich manoeuvre can be used in older children. A foreign body is suggested by: a unilateral wheeze, decreased transmitted breath sounds and a hyperinflated lung from air trapping on an expiratory chest x-ray (Figure 8.21). A rigid bronchoscopy with a ventilating bronchoscope and appropriate optical forceps are needed to assess and remove objects (Summary box 8.16).

Figure 8.20 A positive Meckel's scan.

Summary box 8.16

Swallowed and inhaled objects

- Most swallowed objects pass spontaneously
- Batteries need watching – they must pass quickly if their contents are not to leak
- Objects jammed in the airway or oesophagus need removing promptly

CONGENITAL MALFORMATIONS

Around 2 per cent of babies are born with one or more major structural anomalies caused by genetic defects or teratogenic insults. Some are diagnosed antenatally and surgeons are involved in prenatal counselling. Termination of pregnancy or a planned delivery in a specialist centre are options for severe malformations. Prenatal diagnosis may include checking the karyotype (e.g. Down syndrome (trisomy 21)) or testing for genetic disorders, such as cystic fibrosis.

The incidence of congenital malformations is variable (Table 8.5). Some examples relevant to the general surgeon are briefly outlined in the following sections.

Oesophageal atresia

A blind proximal pouch with a distal tracheo-oesophageal fistula is the most common type (Figure 8.22). Affected infants present soon after birth with drooling and cyanotic episodes on attempting to feed. There may have been polyhydramnios due to failure to swallow amniotic fluid. The diagnosis is confirmed when a nasogastric tube goes no further than the upper oesophageal pouch on the chest x-ray and abdominal gas signifies the

John Langdon Haydon Down (sometimes given as Langdon-Down), 1838–1896, physician, The London Hospital, London, UK, published 'Observations on an ethnic classification of idiots' in 1866.

Figure 8.21 An inspiratory (left) and expiratory (right) chest radiograph demonstrating left-sided pulmonary air trapping after inhalation of a radiolucent foreign body.

tracheo-oesophageal fistula (Figure 8.22). Associated anomalies are common and include cardiac, renal and skeletal defects. Repair is usually via a right-sided extrapleural thoracotomy within a day or two of birth. The fistula is divided and the tracheal side closed. The oesophageal ends are then anastomosed. Postoperative complications include anastomotic leak, stricture, recurrent fistula formation and gastro-oesophageal reflux. Infants with pure oesophageal atresia and no tracheo-oesophageal fistula are usually best managed by a temporary gastrostomy and delayed primary repair or an oesophageal replacement. Except for very-low-birth weight babies and those with major congenital heart disease, most infants with repaired oesophageal atresia have a good prognosis.

Congenital diaphragmatic hernia

Typically in congenital diaphragmatic hernia (CDH), there is a left-sided posterolateral diaphragmatic defect allowing herniation of abdominal viscera into the chest (Figure 8.23). Many are detected antenatally and the prognosis relates to the severity of the associated pulmonary hypoplasia. Despite intensive respiratory support or extracorporeal membrane oxygenation (ECMO), up to 30 per cent of babies with a CDH die from res-

Table 8.5 Incidence of selected malformations.

	Abnormality	Incidence
Thoracic	Congenital diaphragmatic hernia	1:3000
	Oesophageal atresia/tracheo-oesophageal fistula	1:3500
Cardiac	Congenital heart disease	1:150
Gastrointestinal	Gastroschisis	1:7500
	Hirschsprung's disease	1:5000
	Anorectal malformations	1:4–5000
Hepatobiliary	Biliary atresia	1:17 000
	Choledochal cyst	1:50 000
Urogenital	Hypospadias	1:300
	Pelviureteric junction dysfunction	1:1000

Figure 8.22 Oesophageal atresia with a distal tracheo-oesophageal fistula.

piratory failure. If the baby can be stabilised, the diaphragmatic defect is repaired. Small diaphragmatic hernias may present with respiratory or gastrointestinal symptoms in later childhood.

Intestinal atresias

Duodenal atresia may take the form of a membrane or the proximal and distal duodenum may be completely separated. Prenatal ultrasound finds a 'double bubble' in the fetal abdomen with polyhydramnios. There is an association with Down syndrome. Postnatally, there is bilious vomiting if the atresia is distal to the ampulla. A plain abdominal x-ray also shows the

Figure 8.23 Left-sided congenital diaphragmatic hernia.

Figure 8.24 Neonatal abdominal x-ray showing the 'double bubble' of duodenal atresia.

double bubble (Figure 8.24). Repair is by duodenoduodenostomy (Figure 8.25). Occasionally, there is a duodenal membrane with a modest central perforation, which may delay symptoms until later childhood.

Jejunal/ileal atresia varies from an obstructing membrane through to widely separated blind-ended bowel ends associated with a mesenteric defect. Small bowel atresias may be single or multiple and are probably secondary to a prenatal vascular or mechanical insult causing sterile infarction of a segment of gut. They present with intestinal obstruction soon after birth. The proximal bowel is often extremely dilated and needs to be tapered or excised prior to anastomosis to the distal bowel (Figure 8.26).

Meconium ileus is a cause of intestinal obstruction from inspissated meconium in the terminal ileum in neonates, most of whom have cystic fibrosis. Meconium is a sterile mixture of epithelial cells, mucin and bile. Babies with uncomplicated meconium ileus (no associated atresia, volvulus or perforation) can sometimes be managed with hyperosmolar contrast enemas to clear the meconium.

Meconium peritonitis is consequent upon a fetal intestinal perforation. The baby is born with a firm, distended, discoloured abdomen and signs of obstruction. An abdominal x-ray shows dilated intestinal loops and areas of calcification. Occasionally, the perforation has resolved spontaneously before birth, but most neonates with meconium peritonitis will need surgery.

Intestinal malrotation. By the 12th week of gestation, the mid-gut has returned to the fetal abdomen from the extra-embryonic coelom and has begun rotating counterclockwise around the superior mesenteric artery axis. In classical **intestinal malrotation**, this process fails; the duodenojejunal flexure lies to the right of the midline and the caecum is central, creating a narrow base for the small bowel mesentery, which predisposes to mid-gut volvulus (Figure 8.27). Malrotation with volvulus is life-threatening and typically presents with bilious vomiting. Bile-stained vomiting in the infant is a sign of intestinal obstruction until proved otherwise.

Figure 8.25 (a) Duodenal atresia and (b) the incisions (A–D) used to repair it.

Figure 8.26 Small bowel atresia.

Figure 8.27 (a) Contrast showing malrotation with a volvulus. (b) The narrow origin of the small bowel mesentery predisposes to mid-gut volvulus.

As the gut strangulates, the baby may pass blood-stained stools and becomes progressively more ill. An upper gastrointestinal contrast study confirms the malrotation (Figure 8.27). Resuscitation and urgent surgery are needed to untwist the volvulus, widen the base of the small bowel mesentery, straighten the duodenum and position the bowel in a non-rotated position with the small bowel on the right and the colon on the left (Ladd's procedure). The appendix is usually removed to avoid leaving it in an abnormal site within the abdomen.

Figure 8.28 A newborn infant with gastroschisis.

Figure 8.29 Exomphalos major.

Abdominal wall defects

Gastroschisis is now the most common anomaly in babies born to mothers under 20 years of age. The fetal gut prolapses through a defect to the right of the umbilicus. At birth, the bowel is non-rotated, foreshortened and covered by a fibrinous peel (Figure 8.28). After reduction of the bowel, which may need to be staged using a silo, and closure of the defect, gastroschisis has a good prognosis, although gut dysmotility delays recovery. Some infants have an intestinal atresia and some boys have undescended testes but other anomalies are rare.

Exomphalos is quite a different anomaly in which the intestines and sometimes the liver are covered with a membranous sac from which the umbilical cord arises (Figure 8.29). It may be associated with chromosomal or cardiac anomalies.

Biliary atresia

In biliary atresia, the extrahepatic bile ducts are occluded causing obstructive jaundice (conjugated hyper-bilirubinaemia) and progressive liver fibrosis in early infancy. It should be considered if jaundice persists after 2 weeks of age. Fat malabsorption can lead to a coagulopathy correctable with vitamin K. An abdominal ultrasound scan may show a small gall bladder and no visible

Figure 8.30 A duplicated colon.

bile ducts and a biliary radionuclide scan may show no excretion. A liver biopsy may show proliferation of small bile ducts. It is treated by a Kasai porto-enterostomy in which the occluded extrahepatic bile ducts are excised and a jejunal Roux loop anastomosed to the hepatic hilum. Effective drainage is more likely with surgery before 8 weeks of age and may obviate the subsequent need for liver transplantation.

Alimentary tract duplications

Alimentary tract duplications are rare. They are usually single, variable in size, and spherical or tubular. Most are located on the mesenteric border of the intestine. Typically, they are lined by alimentary tract mucosa and share a common smooth muscle wall and blood supply with the adjacent bowel, with which they may communicate. Duplications can contain heterotopic gastric mucosa and be associated with spinal anomalies. Most duplications present in infancy or early childhood with intestinal obstruction, haemorrhage, intussusception or perforation (Figure 8.30). Rarely, they present in adults and sometimes with a malignancy which has been reported more often with rectal duplication cysts. Complete excision is the treatment of choice.

Hirschsprung's disease

Hirschsprung's disease is characterised by the congenital absence of intramural ganglion cells (aganglionosis) and the presence of hypertrophic nerves in the distal large bowel. The absence of ganglion cells is due to a failure of migration of vagal neural crest cells into the developing gut. The affected gut is in spasm causing a functional bowel obstruction. The aganglionosis is restricted to the rectum and sigmoid colon in 75 per cent of patients (short segment), involves the proximal colon in 15 per cent (long segment) and affects the entire colon and a portion of terminal ileum in 10 per cent (total colonic aganglionosis). A transition zone exists between the dilated, proximal, normally innervated bowel and the narrow, distal aganglionic segment.

Hirschsprung's disease may be familial or associated with Down syndrome or other genetic disorders. Gene mutations

Figure 8.31 Barium enema in an infant showing a 'transition zone' in the proximal sigmoid colon between the dilated proximal normally innervated bowel and the contracted aganglionic rectum.

have been identified on chromosome 10 (involving the *RET* proto-oncogene) and on chromosome 13 in some patients. Hirschsprung's disease typically presents in the neonatal period with delayed passage of meconium, abdominal distension and bilious vomiting, but it may not be diagnosed until later in childhood or even adult life, when it manifests as severe chronic constipation. Enterocolitis is a potentially fatal complication of the disease.

The diagnosis requires an adequate rectal biopsy and an experienced pathologist. A contrast enema may show the narrow aganglionic segment, a cone and the dilated proximal bowel (Figure 8.31). Surgery aims to remove the aganglionic segment and 'pull-through' ganglionic bowel to the anus (e.g. Swenson, Duhamel, Soave and transanal procedures) and can be done in a single stage or in several stages after first establishing a proximal stoma in normally innervated bowel. Most patients achieve good bowel control, but a significant minority experience residual constipation and/or faecal incontinence or further enterocolitis.

Anorectal malformations

The anus is either imperforate or replaced by a fistula which does not pass through the muscle complex and opens away from the specialised skin which represents the true anal site. The sacrum and genitourinary tract are often abnormal. In boys, there may be a rectoperineal fistula, but the most common anomaly is an imperforate anus with a rectobulbar urethral fistula (Figure 8.32). In girls, the most common anomalies are a fistula opening in the posterior vestibule behind the vagina or on the perineum. Cloacal malformations, in which the rectum and genitourinary tract share a common outflow channel, are also seen in girls.

Figure 8.32 (a) An imperforate anus in a neonate associated with (b) a rectourethral fistula, visible on a contrast study performed via a sigmoid colostomy. The bladder is filled with contrast via the fistula and the radio-opaque dot has been placed on the infant's perineum over the normal site of the anus. B, bladder; R, rectum.

Where there is a fistula, meconium can be passed and the diagnosis can be delayed for months because the perineum has not been inspected carefully. Most low malformations are treated by an anoplasty soon after birth. Higher, more complex defects need a temporary colostomy, detailed investigation and then reconstructive surgery. Functional outcome is related to the type of malformation (low defects are associated with constipation, higher defects with faecal incontinence) and the integrity of the sacrum and pelvic muscles. For children with residual intractable faecal incontinence, antegrade colonic enemas administered via a catheterisable appendicostomy (Figure 8.33) (the Malone/

Figure 8.33 Appendicostomy for the delivery of antegrade colonic enemas.

ACE procedure) enable the child to achieve social continence. Causes of intestinal obstruction are summarised below (Summary box 8.17).

Summary box 8.17

Congenital causes of intestinal obstruction

- Intestinal atresia: may be multiple
- Cystic fibrosis: can present with intestinal obstruction from inspissated meconium
- Intestinal malrotation: predisposes to potentially lethal midgut volvulus
- Alimentary tract duplications: may present with obstruction, haemorrhage or intussusception
- Hirschsprung's disease: typically presents with delay in passing meconium after birth
- Anorectal malformations

Urinary tract malformations

Many of these malformations are now detected by prenatal ultrasound scan. Others present in childhood with urinary infection, obstruction or an abdominal mass. Urinary tract disorders in children are investigated by urine microscopy and culture, ultrasound scan, assessment of renal function and a combination of radioisotope renography (uptake and excretion), contrast radiology and endoscopy.

In many infants, prenatally diagnosed mild to moderate hydronephrosis resolves spontaneously. Those with more significant pelviureteric junction obstruction may be asymptomatic or present in later childhood with urinary tract infection or loin pain. Pyeloplasty is indicated for symptoms or impaired

Figure 8.34 Operative appearance of neonatal necrotising enterocolitis.

renal function. In boys, partial membranous obstruction in the posterior urethra (valves) can cause a severe prenatal obstructive uropathy. This condition demands urgent investigation and treatment soon after birth to preserve bladder and kidney function. Renal failure develops in about one-third of affected boys despite early endoscopic ablation of the obstructing valves. Other congenital urinary tract malformations include ureteric abnormalities (e.g. duplex, ureterocoele, vesicoureteric reflux), multicystic dysplastic kidney and bladder exstrophy.

Necrotising enterocolitis is an acquired inflammatory condition of the neonatal gut, mostly affecting premature infants. Immaturity, formula feeds (breast milk is protective), bacterial infection and impaired gut blood flow are implicated in the pathogenesis. The neonate becomes septic with abdominal distension, bloody stools and bilious aspirates. Patchy or extensive pneumatosis intestinalis progresses to necrosis and perforation (Figure 8.34). It commonly affects the terminal ileum and colon. Small intestinal loss can be sufficient to cause severe intestinal failure. Milder cases respond to antibiotics, gut rest and parenteral nutrition, but severe cases need an urgent laparotomy. The mortality remains over 30 per cent.

PAEDIATRIC SURGICAL ONCOLOGY

Although less common in children than adults, neoplasms are a leading cause of death (along with trauma) in those over one year of age. In the western countries, leukaemia, central nervous system (CNS) tumours, lymphomas, neuroblastomas and nephroblastomas account for most paediatric malignancies. Neuroblastoma and nephroblastoma are among the more common solid abdominal tumours. The prognoses for these cancers have improved after numerous multicentre trials.

Neuroblastoma is a malignancy of neuroblasts in the adrenal medulla or sympathetic ganglia and typically presents as an abdominal or paravertebral mass. These cells metastasise to lymph nodes, bone and the liver, and they raise urinary catecholamine levels. Small localised tumours are excised. More

advanced tumours require surgery after chemotherapy. Survival relates to tumour biology and stage (>90 per cent for small localised tumours, <50 per cent for advanced tumours).

Wilms' tumour (nephroblastoma) is a malignant renal tumour derived from embryonal cells; it typically affects children aged from one to four years. A mutation in the Wilms' tumour suppressor gene (*WT1*) is responsible for some cases. It usually presents as an abdominal mass. The tumour extends into the renal vein and vena cava and metastasises to lymph nodes and lungs. Treatment is with chemotherapy and surgery. Survival depends on tumour spread, completeness of excision and the histological appearance, but exceeds 70 per cent even with advanced tumours.

SAFEGUARDING

All staff must be able to recognise abuse and neglect, and know the law and their local child safeguarding contacts. In the UK, three children die each week from neglect or abuse and half of these are at the hands of their parents. One per cent of accident and emergency attendances are from abuse. Consider abuse if any of the following are present:

- bruises away from bony prominences (face, back, abdomen, arms, buttocks, ears and hands);
- bruises in clusters or in the pattern of an implement;
- multiple injuries at different stages of healing;
- different types of injury (e.g. soft tissue, burns or scalds, cuts and bruises);
- rib fractures; bite marks (it is difficult to distinguish adult from child bites, but adult bites are associated with fatal abuse);
- significant delay between the injury and seeking medical advice;
- an inconsistent or vague history;
- inappropriate parental behaviour.

ACKNOWLEDGEMENTS

This chapter owes much to the framework laid by Professor Mark Stringer who wrote the two previous editions.

Principles of oncology

LEARNING OBJECTIVES

To understand:

- The biological nature of cancer
- The principles of cancer prevention and early detection

To appreciate:

- The principles of cancer aetiology and the major known causative factors

- The likely shape of future developments in cancer management
- The multidisciplinary management of cancer
- The principles of palliative care

WHAT IS CANCER?

History

The name 'cancer' comes from the Greek and Latin words for a crab, and refers to the claw-like blood vessels extending over the surface of an advanced breast cancer.

The study of cancer has always been part of clinical medicine: theories have moved from divine intervention, through the humours, and are now firmly based on the cellular origin of cancer. Rudolf Virchow is credited with being the first to demonstrate that cancer is a disease of cells that progresses as a result of abnormal proliferation encapsulated by his famous dictum '*omnis cellula e cellula*' (every cell from a cell). In 1914, Theodor Boveri pointed out the importance of chromosomal abnormalities in cancer cells and, by the 1940s, Oswald Avery had shown that DNA was the genetic material within the chromosomes. In 1953, the key discovery by Watson and Crick of the structure of DNA paved the way for the study of what has become known as the molecular biology of cancer enabling us to investigate, and, in some cases, understand, the biochemical mechanisms whereby cancer cells are formed and which mediate their abnormal behaviour.

The psychopath within

Cancer cells are psychopaths. They have no respect for the rights of other cells. They violate the democratic principles of

normal cellular organisation. Their proliferation is uncontrolled; their ability to spread is unbounded. Their inexorable, relentless progress destroys first the tissue and then the person.

In order to behave in such an unprincipled fashion, cells have to acquire a number of characteristics before they are fully malignant. No one characteristic is sufficient, and not all characteristics are necessary. These features, based on an article by Hanahan and Weinberg, are given in Summary box 9.1.

Summary box 9.1

Malignant transformation

- Establish an autonomous lineage:
 - resist signals that inhibit growth
 - acquire independence from signals stimulating growth
- Obtain immortality
- Evade apoptosis
- Acquire angiogenic competence
- Acquire the ability to invade
- Acquire the ability to disseminate and implant
- Evade detection/elimination
- Genomic instability
- Jettison excess baggage
- Subvert communication to and from the environment/milieu
- Develop ability to change energy metabolism

Establish an autonomous lineage

This involves developing independence from the normal signals that control supply and demand. The healing of a wound is a physiological process; the cellular response is exquisitely coordinated so that proliferation occurs when it is needed and ceases

Francis Harry Compton Crick, 1916–2004, a British molecular biologist who worked at the Cavendish Laboratory, Cambridge, UK and later at the Salk Institute, San Diego, CA, USA. Watson and Crick shared the 1962 Nobel Prize for Physiology or Medicine with Maurice Hugh Frederick Wilkins, 1916–2004, of King's College, London.

Rudolf Ludwig Carl Virchow, 1821–1902, Professor of Pathology, Berlin, Germany.

Theodor Heinrich Boveri, 1862–1913, Professor of Zoology and Comparative Anatomy, Würzburg, Germany.

Oswald Theodore Avery, 1877–1955, a bacteriologist at the Rockefeller Institute, New York, NY, USA.

James Dewey Watson, born 1928, an American biologist who worked at Cambridge, UK, and later became Director of the Cold Spring Harbor Laboratory, New York, NY, USA.

Douglas Hanahan, born 1951, American biologist and director of the Swiss Institute for Experimental Cancer Research (ISREC), Lausanne, Switzerland.

Robert A Weinberg, born 1942, The Whitehead Institute of Biomedical Research and Department of Biology, The Massachusetts Institute of Technology, Cambridge, MA, USA.

when it is no longer required. The whole process is controlled by a series of signals telling cells when to divide and when not to divide. Cancer cells escape from this normal system of checks and balances: they grow and proliferate in the absence of external stimuli regardless of signals telling them not to do so. Oncogenes, an aberrant form of normal cellular genes, are a key factor in this process. They were originally identified as sequences within the genome of viruses that could cause cancer and initially thought to be viral in origin but, surprisingly, turned out to be parts of the normal genome that were hitch-hiking between cells, using the virus as a vector. Viral oncogenes (*v-onc*) had sequence homology with normal cellular genes (*c-onc*) and are now presumed to be mutated versions of genes concerned with normal cellular husbandry. The implication of this is that we all carry within us genetic sequences that, through mutation, can turn into active oncogenes and thereby cause malignant transformation.

Obtain immortality

According to the Hayflick hypothesis, normal cells are permitted to undergo only a finite number of divisions. For humans, this number is between 40 and 60. The limitation is imposed by the progressive shortening of the end of the chromosome (the telomere) that occurs each time a cell divides. Telomeric shortening is like a molecular clock and, when its time is up, the lineage will die out. Cancer cells can use the enzyme telomerase to rebuild the telomere at each cell division, so there is no telomeric shortening and the lineage will never die out. The cancer cell has achieved immortality.

Evade apoptosis

Apoptosis is a form of programmed cell death which occurs as the direct result of internal cellular events instructing the cell to die, rather than external events. Unlike necrosis, apoptosis is an orderly process. The cell dismantles itself neatly for disposal (Figure 9.1). There is a minimal inflammatory response. Apoptosis is a physiological process rediscovered in 1972 and named from the Greek *αποπτωσις*, meaning the act of falling. Cells that find themselves in the wrong place normally die by apoptosis and this is an important self-regulatory mechanism in growth and development. Genes, such as *p53*, that can activate apoptosis function as tumour suppressor genes. Loss of function in a tumour suppressor gene will contribute to malignant transformation. Cancer cells will be able to evade apoptosis, which means that the wrong cells can be in the wrong places at the wrong times.

Acquire angiogenic competence

A mass of tumour cells cannot, in the absence of a blood supply, grow beyond a diameter of about 1 mm. This places a severe restriction on the capabilities of the tumour: it cannot grow much larger or spread widely within the body. If, however, the mass of tumour cells is able to attract or construct a blood supply, then it may then quit its dormant state and behave in a far more aggressive fashion. The ability of a tumour to form blood vessels is termed 'angiogenic competence' and is a key feature of malignant transformation.

Figure 9.1 Electron micrograph of apoptotic bodies engulfed by a macrophage.

Acquire the ability to invade

Cancer cells have no respect for the structure of normal tissues. They acquire the ability to breach the basement membrane and thus gain direct access to blood and lymph vessels using three main mechanisms to facilitate invasion: (1) they cause a rise in the interstitial pressure within a tissue; (2) they secrete enzymes that dissolve extracellular matrix; and (3) they acquire motility. Unrestrained proliferation and a lack of contact inhibition enable cancer cells to exert pressure directly on the surrounding tissue and push themselves beyond normal limits. They secrete collagenases and proteases that chemically dissolve any extracellular boundaries that would otherwise limit their spread through tissues and by modulating the expression of cell surface molecules called integrins, are able to detach themselves from the extracellular matrix. The abnormal integrins associated with malignancy can also transmit signals from the environment to the cytoplasm and nucleus of the cancer cells ('outside-in signalling'), and these signals can induce increased motility.

Acquire the ability to disseminate and implant

Once cancer cells gain access to vascular and lymphovascular spaces, they have acquired the potential to use the body's natural transport mechanisms to distribute themselves throughout the body, although this will not, of itself, cause tumours to develop at distant sites. They also need to acquire the ability to implant. As Paget pointed out over a century ago, there is a crucial relationship here between the seed (the tumour cell) and the soil (the distant tissue). Most of the cancer cells discharged into the circulation probably do not form viable metastases: circulating cancer cells can be identified in patients who never develop clinical evidence of metastatic disease. Clumping may be important in permitting metastases: outer cells protecting inner cells from immunological attack. These outer protective cells may, on occasion, be normal lymphocytes.

Leonard Hayflick, born 1928, while working at the Wistar Institute in Philadelphia in 1962, he noted that normal mammalian cells growing in culture had a limited, rather than an indefinite, capacity for self-replication.

Cancer can spread in this embolic fashion, but also when individual cells migrate and implant. Whether spread occurs in groups or individually, the cells still have to cross the vascular endothelium (and basement membrane) to gain access to the tissue itself. Cancer cells probably implant themselves in distant tissues by exploiting, and subverting, the normal inflammatory response. By expressing inflammatory cytokines, the cancer cells can fool the endothelium of the host tissue into becoming activated and allowing cancer cells access to the extravascular space. Activated endothelium expresses receptors that bind to integrins and selectins on the surface of leukocytes, and this allows the leukocytes to move across the endothelial barrier.

Evade detection/elimination

Cancer cells are simultaneously both 'self' and 'not self'. Although derived from normal cells ('self'), they are, in terms of their genetic make up, behaviour and characteristics, foreign ('not self'). As such, they ought to provoke an immune response and be eliminated and it is entirely possible that malignant transformation is a more frequent event than the emergence of clinical cancer. The possible role of the immune system in eliminating nascent cancers was proposed by Paul Ehrlich in 1909 and revisited by both Sir Frank McFarlane Burnet and Lewis Thomas in the late 1950s. Cancer cells, or at least those that give rise to clinical disease, appear to gain the ability to escape detection by the immune system. This may be by suppressing the expression of tumour-associated antigens, or it may be through actively coopting one part of the immune system to help the tumour to escape detection by other parts of the immune surveillance system.

Genomic instability

A cancer is a genetic ferment. Cells are dividing without proper checks and balances. Mutations are arising all the time and some, particularly those in tumour suppressor genes, may have the ability to encourage the development and persistence of further mutations. This gives rise to the phenomenon of genomic instability – as it evolves, a cancer contains an increasing variety and number of genetic aberrations: the greater the number of such abnormalities, the greater the chance of increasingly deviant behaviour.

Jettison excess baggage

Cancer cells are geared to excessive and remorseless proliferation. They do not need to develop or retain those specialised functions that make them good cellular citizens. They can therefore afford to repress or permanently lose those genes that control such functions. This may bring some short-term advantages. The longer-term disadvantage is that what is today superfluous

may, tomorrow, be essential. This can leave cancer cells vulnerable to external stress and may, in part, explain why some cancer treatments work.

Subvert communication to and from the environment/milieu

Providing false information is a classic military strategy. Degrading the command and control systems of the enemy is an essential component of modern warfare. Cancer cells almost certainly use similar tactics in their battle for control over their host. Given the complexity of communication between and within cells, this is not an easy statement to prove or disprove. Nor does it offer any easy targets for therapeutic manipulation.

Develop ability to change energy metabolism

Blood flow in tumours is often sporadic and unreliable. As a result, cancer cells may have to spend prolonged periods starved of oxygen – in a state of relative hypoxia. Compared to the corresponding normal cells, some cancer cells may be better able to survive in hypoxic conditions. This ability may enable tumours to grow and develop despite an impoverished blood supply. Cancer cells can alter their metabolism even when oxygen is abundant, they break down glucose but do not, as normal cells would do, send the resulting pyruvate to the mitochondria for conversion, in an oxygen-dependent process, to carbon dioxide. This is the phenomenon of aerobic glycolysis, or the Warburg effect and leads to the production of lactate. In an act of symbiosis, lactate-producing cancer cells may provide lactate for adjacent cancer cells which are then able to use it, via the citric acid cycle, for energy production. This cooperation is similar to that which occurs in skeletal muscle during exercise.

Malignant transformation

The characteristics of the cancer cell arise as a result of mutation. Only very rarely is a single mutation sufficient to cause cancer; multiple mutations are usually required. Colorectal cancer provides the classical example of how multiple mutations are necessary for the complete transformation from normal to malignant cell. Vogelstein and colleagues identified the genes required and also postulated not only that it is necessary to have mutations in all the relevant genes, but also that these mutations must be acquired in a specific sequence.

Cancer is usually regarded as a clonal disease. Once a cell has arisen with all the mutations necessary to make it fully malignant, it is capable of giving rise to an infinite number of identical cells, each of which is fully malignant. These cells divide, invade, metastasise and destroy but, ultimately, each is the direct descendant of that original, primordial, transformed cell. There is certainly evidence, mostly from haematological malignancies,

Stephen Paget, 1855–1926, surgeon, The West London Hospital, London, UK. Paget's 'seed and soil' hypothesis is contained in his paper 'The distribution of secondary growths in cancer of the breast', in the *Lancet*, 1889.

Paul Ehrlich, 1854–1915, Professor of Hygiene, The University of Berlin, and later Director of The Institute for Infectious Diseases, Berlin, Germany. In 1908, he shared the Nobel Prize for Physiology or Medicine with **Elie Metchnikoff**, 1845–1916, 'in recognition of his work on immunity'. Metchnikoff was Professor of Zoology at Odessa in Russia, and later worked at the Pasteur Institute in Paris, France.

Sir Frank McFarlane Burnett, 1899–1985, an Australian virologist, at the Walter and Eliza Hall Institute, Melbourne, Australia. Burnett shared the 1960 Nobel Prize for Physiology or Medicine with **Sir Peter Brian Medawar**, 1915–1987, Jodrell Professor of Zoology, University College, London, UK, 'for their discovery of acquired immunological tolerance'.

Otto Warburg, 1883–1970, chemist, Director of the Kaiser Wilhelm Institute for Cell Physiology, Berlin-Dahlem. Awarded the Nobel Prize for Physiology or Medicine in 1931 for 'his discovery of the nature and mode of action of the respiratory enzyme'.

Lewis Thomas, 1913–1993, an American pathologist and immunologist, who became President of the Sloan Kettering Memorial Institute, New York, NY, USA.
Bert Vogelstein, born 1949, molecular biologist, Johns Hopkins Hospital, Baltimore, MD, USA.

to support the view that tumours are monoclonal in origin, but recent evidence challenges the universality of this assumption. Some cancers may arise from more than one clone of cells. Epigenetic modification refers to heritable changes in DNA that are not related to the nucleotide sequence of the molecule. Epigenetic modification may give rise to distinct cancer cell lineages with differing biological properties. The interactions between cells from each lineage and the tissue within which such cells find themselves may determine the overall clinical behaviour of a tumour.

Two mechanisms may help to sustain and accelerate the process of malignant transformation: genomic instability and tumour-related inflammation.

Genomic instability

If a tumour is a genetic ferment, then there is abundant opportunity for mutations to occur in the DNA of tumour cells, some of these mutations (for example, those occurring in tumour suppressor genes) may themselves be capable of facilitating the persistence of further mutations and so the pace of malignant transformation can be accelerated.

Tumour-related inflammation

If a tumour provokes an inflammatory response, then the cytokines and other factors produced as a result of that response may act to promote and sustain malignant transformation. Growth factors, mutagenic ROS (reactive oxygen species), angiogenic factors, anti-apoptotic factors, may all be produced as part of an inflammatory process and all may contribute to the progression of a tumour.

A recurring theme in the molecular biology of cancer is that systems and pathways can behave unpredictably – activation may sometimes promote, and sometimes inhibit, growth and transformation. This has important implications for therapy – treatments designed to inhibit the growth and spread of cancer may, occasionally, have precisely the opposite effect. The most consistent feature of cancer is its lack of consistency.

The growth of a tumour

If it is accepted that a cancer starts from a single transformed cell, then it is possible, using straightforward arithmetic, to describe the progression from a single cell to a mass of cells large enough to kill the host. The division of a cell produces two daughter cells. The relationship 2^n will describe the number of cells produced after n generations of division. There are between 10^{13} and 10^{14} cells in a typical human being. A tumour 10 mm in diameter will contain about 10^9 cells. As $2^{30} = 10^9$, this implies that it would take 30 generations to reach the threshold of clinical detectability and, as $2^{45} = 3 \times 10^{13}$, fewer than 15 subsequent generations to produce a tumour that, through sheer bulk alone, would be fatal. This is an oversimplification because cell loss is a feature of many tumours and, for squamous cancers, as many as 99 per cent of the cells produced may be lost, mainly by exfoliation. It will, in the presence of cell loss, take many cellular divisions to produce a clinically evident tumour – abundant opportunity for further mutations to occur during the preclinical phase of tumour growth. The growth of a typical human tumour can be described by an exponential relationship, the doubling time of which increases exponentially – so-called Gompertzian

growth (Figure 9.2). This Gompertzian pattern has several important implications for the diagnosis and treatment of cancer (Summary box 9.2).

Summary box 9.2

Clinical implications of Gompertzian growth

- The majority of the growth of a tumour occurs before it is clinically detectable
- By the time they are detected, tumours have passed the period of most rapid growth, that period when they might be most sensitive to anti-proliferative drugs
- There has been plenty of time, before diagnosis, for individual cells to detach, invade, implant and form distant metastases – in many patients cancer may, at presentation, be a systemic disease.
- 'Early tumours' are genetically old: plenty of time for mutations to have occurred, mutations that might confer spontaneous drug resistance (a probability greatly increased by the existence of cell loss)
- The rate of regression of a tumour will depend upon its age (the Norton–Simon hypothesis extends this: the rate of regression of a tumour will depend upon its growth rate at the time of treatment)

Figure 9.2 The Gompertzian curve describing the growth of a typical tumour. In its early stages, growth is exponential but, as the tumour grows, the growth rate slows. This decrease in growth rate probably arises because of difficulties with nutrition and oxygenation. The tumour cells are in competition: not only with the tissues of the host, but also with each other.

Benjamin Gompertz, 1779–1865, an insurance actuary who was interested in calculating annuities. To do this, he needed to describe mathematically the relationship between life-expectancy and age. He was able to do this using the function that bears his name. The Gompertzian function provides an excellent fit to data points plotting tumour size against time.

THE CAUSES OF CANCER

The interplay between nature and nurture

Both inheritance and environment are important determinants of cancer development. Although environmental factors have been implicated in more than 80 per cent of cases, this still leaves plenty of scope for the role of genetic inheritance: not just the 20 per cent of tumours for which there is no clear environmental contribution but also, as environment alone can rarely

cause cancer, the genetic contribution to the 80 per cent of tumours to which environmental factors contribute.

Knowledge about the causes of cancer can be used to design appropriate strategies for prevention or earlier diagnosis. As more is discovered about the genes associated with cancer, genetic testing and counselling will play an increasing role in its prevention. These considerations are incorporated into Table 9.1 on the inherited cancer syndromes, and Table 9.2 on the environmental contribution to cancer.

Table 9.1 Inherited syndromes associated with cancer.

Syndrome	Gene(s) implicated	Inheritance	Associated tumours and abnormalities	Strategies for prevention/early diagnosis
Familial adenomatous polyposis (FAP)/Gardner syndrome	APC gene	D	Colorectal cancer under the age of 25 years Papillary carcinoma of the thyroid Cancer of the ampulla of Vater Hepatoblastomas Primary brain tumours (Turcot's syndrome) Osteomas of the jaw CHRPE (congenital hypertrophy of the retinal pigment epithelium)	Prophylactic panproctocolectomy
Hereditary non-polyposis colorectal cancer (HNPCC)	DNA mismatch repair genes (MLH1, MSH2, MSH6)	D	Colorectal cancer (typically in the 40s and 50s)	Surveillance colonoscopies/ polypectomies Non-steroidal anti-inflammatory drugs
HNPCC1	MSH2		Endometrium, stomach, hepatobiliary (Lynch's syndrome 1)	
HNPCC2	MLH1			
HNPCC3	PMS1			
Peutz-Jeghers syndrome	STK11	D	Bowel cancer, breast cancer, freckles round the mouth	Surveillance colonoscopy, mammography
Cowden's syndrome	PTEN	D	Multiple hamartomas of skin, breast and mucus membranes Breast cancer Neuroendocrine tumours Endometrial cancer, thyroid cancer	Active surveillance
Retinoblastoma	RB	D	Retinoblastoma Pinealoma Osteosarcoma	Surveillance of the uninvolved eye
Multiple endocrine neoplasia (MEN) type 1	Menin	D	Parathyroid tumours Islet cell tumours Pituitary tumours	Awareness of associations and paying attention to relevant symptoms
MEN type 2A	RET	D	Medullary carcinoma of the thyroid Pheochromocytoma Parathyroid tumours	Regular screening of blood pressure, serum calcitonin and urinary catecholamines Prophylactic thyroidectomy

Eldon J Gardner, born 1909, Professor of Zoology, Utah State University, Salt Lake City, UT, USA.

Abraham Vater, 1684–1751, Professor of Anatomy and Botany, and later of Pathology and Therapeutics, Wittenburg, Germany.

Jacques Turcot, born 1914, surgeon, Hôtel Dieu de Québec Hospital, Québec, Canada.

Henry T Lynch, born 1928, oncologist, Chairman of the Department of Preventive Medicine, Creighton School of Medicine, California, USA.

John Law Augustine Peutz, 1886–1968, Chief Specialist for Internal Medicine, St John's Hospital, The Hague, The Netherlands.

Harold Joseph Jeghers, 1904–1990, Professor of Internal Medicine, The New Jersey College of Medicine and Dentistry, Jersey City, NJ, USA.

One of the few clinical syndromes named after the patient rather than the clinician, **Rachel Cowden** was, in 1963, the first patient described with the syndrome. She died from breast cancer at the age of 20.

Table 9.1 Inherited syndromes associated with cancer – *continued*.

Syndrome	Gene(s) implicated	Inheritance	Associated tumours and abnormalities	Strategies for prevention/early diagnosis
MEN type 2b	<i>RET</i>	D	Medullary carcinoma of the thyroid Pheochromocytoma Mucosal neuromas Ganglioneuromas of the gut	Regular screening of blood pressure, serum calcitonin and urinary catecholamines Prophylactic thyroidectomy
Li–Fraumeni syndrome	<i>p53</i>	D	Sarcomas Leukaemia Osteosarcomas Brain tumours Adrenocortical carcinomas	Very difficult, as the pattern of tumours is so heterogeneous and varies from patient to patient
Familial breast cancer	<i>BRCA1, BRCA2</i>	D	Breast cancer Ovarian cancer Papillary serous carcinoma of the peritoneum Prostate cancer	Screening mammography Pelvic ultrasound Prostate-specific antigen in males Prophylactic mastectomy Prophylactic oophorectomy
Familial cutaneous malignant melanoma	<i>CDNK2A, CDK4</i>	D	Cutaneous malignant melanoma	Avoid exposure to sunlight, careful surveillance
Basal cell naevus syndrome (Gorlin)	<i>PTCH</i>	D	Basal cell carcinomas Medulloblastoma Bifid ribs	Careful surveillance, awareness of diagnosis (look for bifid ribs on x-ray)
Von Hippel–Lindau syndrome	<i>VHL</i>	D	Renal cancer Pheochromocytoma Haemangiomas of the cerebellum and retina	Urinary catecholamines
Neurofibromatosis type 1	<i>NF1</i>	D	Astrocytomas Primitive neuroectodermal tumours Optic gliomas Multiple neurofibromas	A difficult problem; maintain a high index of suspicion concerning any rapid changes in the growth or character of any nodule
Neurofibromatosis type 2	<i>NF2</i>	D	Acoustic neuromas Spinal tumours Meningiomas Multiple neurofibromas	
Xeroderma pigmentosum	Deficient nucleotide excision repair (XPA, B, C)	R	Skin sensitive to sunlight; early onset of cutaneous carcinomas (SCCs, BCCs)	Avoidance of sun exposure Active surveillance and early treatment Retinoids for chemoprevention
Ataxia telangiectasia	<i>AT</i>	R	Progressive cerebellar ataxia Leukaemia Lymphoma Breast Melanoma Upper gastrointestinal	Active surveillance
Bloom's syndrome	<i>BIM helicase</i>	R	Sensitivity to UV light Leukaemia Lymphoma	Active surveillance

BCC, basal cell carcinoma; D, dominant; R, recessive; SCC, squamous cell carcinoma; UV, ultraviolet.

Frederick P Li, born 1940, Professor of Medicine, Harvard University Medical School, Boston, MA, USA.

Joseph F Fraumeni, born 1933, Director of Cancer Epidemiology and Genetics, The National Cancer Institute, Bethesda, MD, USA.

Robert Gorlin, 1923–2006, Professor of Dentistry, The University of Minnesota, Minneapolis, MN, USA.

Eugen von Hippel, 1867–1939, Professor of Ophthalmology, Göttingen, Germany.

Arvid Lindau, 1892–1958, Professor of Pathology, Lund, Sweden.

David Bloom, born 1892, a dermatologist at the Skin and Cancer Clinic, New York University, New York, NY, USA, described the syndrome in 1954.

Table 9.2 Environmental causes of cancer (and suggested measures for reducing their impact).

Environmental/behavioural factor			Associated tumours	Strategy for prevention/early diagnosis
Tobacco			Lung cancer Head and neck cancer	Ban tobacco Ban smoking in public places Punitive taxes on tobacco
Alcohol			Head and neck cancer Oesophageal cancer Hepatoma	Avoid excess alcohol Surveillance of high-risk individuals
UV exposure			Melanoma Non-melanoma skin cancer	Avoid excessive sun exposure, avoid sunbeds
Ionising radiation			Leukaemia Breast Lymphoma Thyroid	Limit medical exposures to the absolute minimum; safety precautions at nuclear facilities; monitor radiation workers
Viral infections	HPV		Cervix Penis	Avoid unprotected sex Vaccination
	HIV		Kaposi's sarcoma Lymphomas Germ cell tumours Anal cancer	Avoid unprotected sex Anti-retroviral therapy
	Hepatitis B		Hepatoma	Avoid contaminated injections/infusions Vaccination
Other infections	Bilharzia		Bladder cancer	Treatment of infection Cystoscopic surveillance
	<i>Helicobacter pylori</i>		Stomach cancer	Eradication therapy
Inhaled particles	Asbestos		Mesothelioma	Protection of exposed workers
	Wood dust		Paranasal sinus cancers	Protection of exposed workers
Chemicals	Environmental pollutants/chemicals used in industry		Angiosarcoma (vinyl chloride) Bladder cancer (aniline dyes, vulcanisation of rubber) Lung, nasal cavity (nickel) Skin (arsenic) Lung (beryllium, cadmium, chromium) All sites (dioxins)	Protection of exposed workers; avoid chemical discharge and spillages
		Medical	Alkylating agents used in cytotoxic chemotherapy Immunosuppressive treatment Stilbestrol Tamoxifen	Avoid overtreatment; only combine drugs with ionising radiation when absolutely necessary As low a dose as possible, for as short a period as possible Use of stilbestrol curtailed Biopsy if patient on tamoxifen develops uterine bleeding
Fungal and plant toxins	Aflatoxins		Hepatoma	Appropriate food storage, screen for fungal contamination of foodstuffs

Table 9.2 Environmental causes of cancer (and suggested measures for reducing their impact) – continued.

Environmental/behavioural factor	Associated tumours	Strategy for prevention/early diagnosis
Obesity/lack of physical exercise	Breast Endometrium Kidney Colon Oesophagus	Maintain ideal body weight, regular exercise

HIV, human immunodeficiency virus; HPV, human papillomavirus; UV, ultraviolet.

THE MANAGEMENT OF CANCER

Management is more than treatment

The traditional approach to cancer concentrates on diagnosis and active treatment. This is a very limited view that, in terms of the public health, may not have served society well. It implies a fatalistic attitude to the occurrence of cancer and an assumption that, once active treatment is complete, there is little more to be done. Prevention is forgotten and rehabilitation ignored. Cancer management can be considered as taking place along two axes: one an axis of scale, from the individual to the world population; the other based on the unnatural history of the disease, from prevention to rehabilitation or palliative care (see Figure 9.3).

Prevention

Table 9.2 summarises the approaches that can be used in the prevention of cancer. In 1998, Sir Richard Doll estimated that 30 per cent of cancer deaths were due to tobacco use and that up to 50 per cent of cancer deaths were related to diet. Even allow-

ing for overlap (smokers often have a poor diet), these are impressive figures and add some perspective to the often inflated claims made for the achievements of cancer treatment. Doll estimated that cancers related to occupation accounted for less than 4 per cent of cancer deaths, and that environmental pollution accounted for less than 5 per cent of deaths.

Screening

Screening involves the detection of disease in an asymptomatic population in order to improve outcomes by early diagnosis. It follows that a successful screening programme must achieve early diagnosis, and that the disease in question has a better outcome when treated at an early stage. The criteria that must be fulfilled for the disease, screening test and the screening programme itself are given in Summary box 9.3.

Summary box 9.3

Criteria for screening

- The disease
 - Recognisable early stage
 - Treatment at an early stage more effective than at a later stage
 - Sufficiently common to warrant screening
- The test
 - Sensitive and specific
 - Acceptable to the screened population
 - Safe
 - Inexpensive
- The programme
 - Adequate diagnostic facilities for those with a positive test
 - High-quality treatment for screen-detected disease to minimise morbidity and mortality
 - Screening repeated at intervals if the disease is of insidious onset
 - Benefit must outweigh physical and psychological harm

Figure 9.3 The management of cancer spans the natural history of the disease and all humankind, from the individual to the population of the world. WHO, World Health Organization.

Sir William Richard Shaboe Doll, 1912–2005, Regius Professor of Medicine, Oxford University, Oxford, UK, and Sir Austin Bradford Hill, Professor of Medical Statistics, The London School of Hygiene and Tropical Medicine, London, UK, published one of the definitive reports linking smoking to lung cancer in 1950.

Merely to prove that screening picks up disease at an early stage, and that the outcome is better for patients with screen-detected disease than for those who present with symptoms, is an insufficient criterion for the success of a screening programme. This is because of inherent biases in screening (lead time bias, selection bias and length bias), which make screen-detected

disease appear to be associated with better outcomes than symptomatic disease. Lead time bias describes the phenomenon whereby early detection of a disease will always prolong survival from the time of diagnosis when compared with disease picked up at a later stage in its development whether or not the screening process has altered the progression of the tumour (Figure 9.4). Selection bias describes the finding that individuals who accept an invitation for screening are, in general, healthier than those who do not. It follows that individuals with screen-detected disease will tend, independently of the condition for which screening is being performed, to live longer. Length bias is brought about by the fact that slow-growing tumours are likely to be picked up by screening, whereas fast-growing tumours are likely to arise and produce symptoms in between screening rounds. Thus, screen-detected tumours will tend to be less aggressive than symptomatic tumours. Because of these biases, it is essential to carry out population-based randomised controlled trials and to compare mortality rate in a whole population offered screening (including those who refuse to be screened and those who develop cancer after a negative test) with mortality rate in a population that has not been offered screening.

Figure 9.4 Lead time and length bias. Tumour 'a' is a steadily growing tumour; its progress is uninfluenced by any treatment. The arrows indicate the timing of tests in a screening programme. The horizontal lines indicate three thresholds: detectability by screening; clinical detectability; and death due to tumour progression. Point A indicates the time at which the tumour would be diagnosed in a screening programme and point B indicates the time at which the tumour would be diagnosed clinically, that is in the absence of any screening programme. If the date of diagnosis is used as the start time for measuring survival, then it is clear that, in the absence of any effect from treatment, the screening programme will artefactually add to the survival time. The amount of 'increased' survival is equal to $y - x$ years, in this example, just over two years. This artefactual inflation of survival time is referred to as lead time bias. Tumour 'b' is a rapidly growing tumour; again, its progress is uninfluenced by treatment. It grows so rapidly that, in the interval between two screening tests, it can cross both the threshold for detectability by screening and that of clinical detectability. It will continue to progress rapidly after diagnosis, and the measured survival time will be short. This phenomenon, whereby those tumours that are 'missed' by the screening programme are associated with decreased survival, is called length bias.

This research design has been applied to both breast cancer and colorectal cancer: in both cases, there was reduction in disease-specific mortality.

Diagnosis and classification

Accurate diagnosis is the key to the successful management of cancer. Diagnosis lies at the heart of the epidemiology of cancer; if there is an inaccurate picture of the pattern of a disease, reliable inferences about its distribution and causes cannot be drawn. Precise diagnosis is crucial to the choice of correct therapy; the wrong operation, no matter how superbly performed, is useless. An unequivocal diagnosis is the key to an accurate prognosis. Only rarely can a diagnosis of cancer confidently be made in the absence of tissue for pathological or cytological examination. Cancer is a disease of cells and, for accurate diagnosis, the abnormal cells need to be seen. Different tumours are classified in different ways: most squamous epithelial tumours are simply classed as well (G1), moderate (G2) or poorly (G3) differentiated (Figure 9.5). Adenocarcinomas are also often classified as G1, 2 or 3, but prostate cancer is an exception with widespread use of the Gleason system. The Gleason system grades prostate cancer according to the degree of differentiation of the two most prevalent architectural patterns. The final score is the sum of the two grades and can vary from 2 (1 + 1) to 10 (5 + 5), with the higher scores indicating poorer prognosis. The management of malignant lymphomas is based firmly upon histopathological classification: the first distinction is between Hodgkin's lymphoma (HL) and non-Hodgkin's lymphoma (NHL). Each of these main types of lymphoma is then subclassified according to a different scheme. The World Health Organization/Revised European-American Lymphoma (WHO/REAL) system classifies Hodgkin's lymphoma into classical HL (nodular sclerosis HL; mixed cellularity HL; lymphocyte depletion HL; lymphocyte-rich classical HL) and nodular lymphocyte-predominant HL. The WHO/REAL classification of NHL is considerably more complex and recognises 27 distinct pathological subtypes. It is perhaps no coincidence that the non-surgical treatment of lymphomas is, by and large, more successful than the non-surgical treatment of solid tumours. This suggests that precise and accurate subtyping of tumours enables appropriate selection of treatment and, in turn, this is associated with better outcome.

Investigation and staging

It is not sufficient simply to know what a cancer is; it is imperative to know its site and extent. If it is localised, then locoregional treatments such as surgery and radiation therapy may be curative. If the disease is widespread, then, although such local interventions may contribute to cure, they will be insufficient, and systemic treatment, for example with drugs or hormones, will be required. Staging is the process whereby the extent of disease is mapped out. Formerly, staging was a fairly crude process, but nowadays it is a highly sophisticated process, heavily reliant on the technology of modern imaging. These technological advances bring with them the implication that patients staged as having localised disease in 2012 are not comparable to patients described in 1985 as having localised disease. Many of these latter patients would have had occult metastatic disease detected had they been imaged using current technology. This

Figure 9.5 Three carcinomas showing different degrees of differentiation. Left to right: well-differentiated, moderately differentiated and poorly differentiated.

leads to the paradox of stage shift, also named the Will Rogers phenomenon by Alvan Feinstein. A change in staging system, or in the techniques used to provide baseline information concerning staging, can produce ‘benefits’ to patients at all stages of the disease. These benefits are, however, entirely artefactual and depend simply upon patients in each stage being enriched by patients with improved prognosis. The important cross-check to protect against being misled by stage shift is that the prognosis for the entire group (i.e. all stages pooled) has not been changed. Table 9.3 shows a worked example of stage shift.

The International Union against Cancer (UICC) is responsible for the TNM (tumour, nodes, metastases) staging

system for cancer. This system is compatible with, and relates to, the American Joint Committee on Cancer (AJCC) system for stage grouping of cancer. Examples of clinicopathological staging systems for colon cancer are shown in Tables 9.4 and 9.5.

Therapeutic decision making and the multidisciplinary team

As the management of cancer becomes more complex, it becomes impossible for any individual clinician to have the intellectual and technical competence that is necessary to manage all the patients presenting with a particular type of

Table 9.3 Stage shift.

Before new staging test				After new staging test				
Stage	Distribution (per cent)	Cure rate (per cent)	Number cured	Stage	Distribution (per cent)	Cure rate (per cent)	Number cured	‘Improvement’ in cure rate (per cent)
I	70	90	63	I	50	94	47	4
II	10	80	8	II	10	80	8	0
III	10	80	8	III	10	80	8	0
IV	10	50	5	IV	30	70	21	20
All	100		84	All	100		84	0

The cure rate improves in both stage I and stage IV, and there is no change in cure rates for stage II and stage III, after the introduction of a new staging investigation. The overall cure rate is, however, unchanged.

Alvan Feinstein, 1926–2001, American Clinician and Epidemiologist.
Will Rogers [properly William Penn Adair Rogers], 1879–1935, American Actor, Humorist and Wit.
There is much confusion about the use of the terms ‘**multidisciplinary**’ and ‘**multiprofessional**’: we use ‘multidisciplinary’ to imply the presence of various medically qualified specialists (pathologists, radiologists, etc.) and ‘multiprofessional’ implies the presence of specialists from non-medical backgrounds (nurses, social workers, radiographers).

Table 9.4 Staging of colorectal cancer.

TNM	
TX, Primary tumour cannot be assessed	
T0, No evidence of primary tumour	
Tis, Intraepithelial or intramucosal carcinoma	
T1, Tumour invades submucosa	
T2, Tumour invades muscularis propria	
T3, Tumour invades through the muscularis propria into the subserosa or into retroperitoneal (pericolic or perirectal) tissues	a, Minimal invasion: <1 mm beyond muscularis b, Slight invasion: 1–5 mm beyond muscularis c, Moderate invasion: >5–15 mm beyond muscularis d, Extensive invasion: >15 mm beyond muscularis
T4, Tumour directly invades beyond bowel	a, Direct invasion into other organs or structures b, Perforates visceral peritoneum
NX, Regional lymph nodes cannot be assessed	
N0, No metastases in regional nodes	
N1, Metastases in 1–3 regional lymph nodes	
N2, Metastases in ≥4 regional lymph nodes	
MX, Not possible to assess the presence of distant metastases	
M0, No distant metastases	
M1, Distant metastases present

tumour. The formation of multidisciplinary teams represents an attempt to make certain that each and every patient with a particular type of cancer is managed appropriately. Teams should not only be multidisciplinary, they should be multiprofessional (Summary box 9.4).

Summary box 9.4

Members of the multiprofessional team

- Site-specialist surgeon
- Surgical oncologist
- Plastic and reconstructive surgeon
- Clinical oncologist/radiotherapist
- Medical oncologist
- Diagnostic radiologist
- Pathologist
- Speech therapist
- Physiotherapist
- Prosthetist
- Clinical nurse specialist (rehabilitation, supportive care)
- Palliative care nurse (symptom control, palliation)
- Social worker/counsellor
- Medical secretary/administrator
- Audit and information coordinator

The advantages and disadvantages of multidisciplinary teams are summarised in Table 9.6.

Principles of cancer surgery

For most solid tumours, surgery remains the definitive treatment and the only realistic hope of cure. However, surgery has several

Table 9.6 The advantages and disadvantages of the multidisciplinary team.

Advantages	Disadvantages
Open debate concerning management	An opportunity for rampant egotism and showing off
Patient has the advantage of many simultaneous opinions from many different specialties	Less confident and less articulate members of the team may not be able to express their views, even though their views may be extremely important
Decision making is open, transparent and explicit	May degenerate into a rubber-stamping exercise in which the class solutions implied by guidelines are unthinkingly applied to disparate individuals
Team members educate each other	Decisions are made in the absence of patients and their carers: the commodification of the person
A useful educational experience for trainees and students	Clinicians are able to avoid having to take responsibility for their decisions and their actions: the figleaf of 'corporate responsibility'
	Time-consuming and resource intensive: takes busy clinicians away from clinical practice for hours at a time

roles in cancer treatment including diagnosis, removal of primary disease, removal of metastatic disease, palliation, prevention and reconstruction.

Diagnosis and staging

In most cases, the diagnosis of cancer has been made before definitive surgery is carried out but, occasionally, a surgical procedure is required to make the diagnosis. This is particularly true of patients with malignant ascites where laparoscopy has an important role in obtaining tissue for diagnosis. Laparoscopy is also widely used for the staging of intra-abdominal malignancy, particularly oesophageal and gastric cancer. By this means, it is often possible to diagnose widespread peritoneal disease and small liver metastases that may have been missed on cross-sectional imaging. Laparoscopic ultrasound is a particularly useful adjunct for the diagnosis of intrahepatic metastases. Other examples in which surgery is central to the diagnosis of cancer include orchidectomy where a patient is suspected of having testicular cancer and lymph node biopsy in a patient with lymphoma. Recently, sentinel node biopsy in melanoma and breast cancer has attracted a great deal of interest. Here, a radiolabelled colloid is injected into or around the primary tumour, and the regional lymph nodes are scanned with a gamma camera that will pinpoint the lymph node nearest to the tumour. This lymph node can then be removed for histological diagnosis. Until recently, staging laparotomy was an important aspect of the staging of lymphomas but, with more accurate cross-sectional imaging and the much more widespread use of chemotherapy, this practice is now largely redundant.

Removal of primary disease

Radical surgery for cancer involves removal of the primary tumour and as much of the surrounding tissue and lymph node drainage as possible in order not only to ensure local control but also to prevent spread of the tumour through the lymphatics. Although the principle of local control is still extremely important, it is now recognised that ultraradical surgery probably has little effect on the development of metastatic disease, as

evidenced by the randomised trials of radical versus simple mastectomy for breast cancer. It is important, however, to appreciate that high-quality, meticulous surgery taking care not to disrupt the primary tumour at the time of excision is of the utmost importance in obtaining a cure in localised disease and preventing local recurrence.

Removal of metastatic disease

In certain circumstances, surgery for metastatic disease may be appropriate. This is particularly true for liver metastases arising from colorectal cancer where successful resection of all detectable disease can lead to long-term survival in about one-third of patients. With multiple liver metastases, it may still be possible to take a surgical approach by using *in situ* ablation with cryotherapy or radiofrequency energy. Another situation where surgery may be of value is pulmonary resection for isolated lung metastases, particularly from renal cell carcinoma.

Palliation

In many cases, surgery is not appropriate for cure but may be extremely valuable for palliation. A good example is the patient with a symptomatic primary tumour who also has distant metastases. In this case, removal of the primary may improve the patient's quality of life, but will have little effect on the ultimate outcome. Other examples include bypass procedures, such as an ileotransverse anastomosis to alleviate symptoms of obstruction caused by an inoperable caecal cancer or bypassing an unresectable carcinoma at the head of the pancreas by cholecysto- or choledochojejunostomy to alleviate jaundice.

Principles underlying the non-surgical treatment of cancer

The relationship between dose and response and the principle of selective toxicity

Non-surgical treatments, in common with surgery, have the potential to cause harm as well as benefit. Surgery is difficult to quantify; it is hard to describe a mastectomy in units of measure.

Both drugs and radiation can be expressed in reproducible units: milligrams in the case of drugs; Grays (Gy) in the case of radiation. Thus, in contrast to surgery, it is possible to construct dose–response relationships for both the benefits (such as tumour cure rate) and harms (such as tissue damage that is both severe and permanent) associated with non-surgical interventions. These curves (see Figure 9.6) have the same general shape: they are sigmoidal. The practical consequence of this is that, over a relatively narrow dose range, we move from failure to success, from tolerability to disaster. In theory, it is possible to calculate an optimal dose for treating each tumour using dose–response curves: the dose is that which is associated with the

maximal probability of an uncomplicated cure. Lying behind the concept of the probability of an uncomplicated cure is the principle of selective toxicity: the treatment should be selectively toxic to the tumour and, as far as possible, should spare the normal tissues from damage. It is this simple principle that underpins both the selection of agents used to treat cancer and the schedules employed to deliver them. Although the graphical representations of the relationships between dose, response and the probability of uncomplicated cure are conceptually simple and intuitively appealing, they are, in clinical practice, impractical. The construction of full dose–response curves for all possible combinations of tumours and normal tissues is neither feasible nor ethical. Reliance, when it comes to defining optimal doses and schedules, must be on incomplete clinical data and a knowledge of the general shape of the relationship between dose and response.

Louis Harold Gray, 1905–1965, director, The British Empire Cancer Campaign Research Unit in Radiobiology, Mount Vernon Hospital, Northwood, Middlesex, UK. A Gray (Gy) is the SI unit for the absorbed dose of ionising radiation.

Figure 9.6 A schematic illustration of the relationship between dose, response and the probability of uncomplicated cure. The upper figures show ideal circumstances with steep dose–response relationships for both normal tissue damage and tumour control. The lower figures show something more like the real world. The dose–response relationship for tumour control is flatter, because tumours are heterogeneous and, consequently, the probability of uncomplicated cure is lower – even for the optimal dose (40 per cent in the lower figure compared with 70 per cent in the upper figure).

Figure 9.7 Schematic diagram to show the spatial scope of cancer treatments. Chemotherapy is systemic; surgery is mainly a local treatment. Radiotherapy is usually local or locoregional, but can, as in radioiodine therapy for thyroid cancer, be systemic.

General strategies in the non-surgical management of cancer

Curative surgery for cancer is guided by one simple principle: the physical removal of all identifiable disease. The principles underlying the non-surgical management of cancer are more complex. First, the spatial distribution of the effects of our therapies have to be considered: surgery and radiotherapy are local or, at best, locoregional treatments; drugs offer a therapy that is systemic (Figure 9.7). Second, there is the question of the intent underlying the treatment. Occasionally, radiotherapy, chemotherapy or the combination of the two may be used with curative intent (Table 9.7). More usually, chemotherapy or radiotherapy is used to lower the risk of recurrence after primary treatment with surgery, so-called adjuvant therapy. Implicit within the concept of adjuvant therapy is the realisa-

tion that much of what is done is unnecessary or futile, or both. The need for adjuvant therapy, to treat the risk that residual disease might be present after apparently curative surgery, is an acknowledgement of the current inability to detect or predict, with sufficient precision, the presence of residual disease. It also explains why the incremental benefits from adjuvant treatments are so small and why the existence of these benefits can only be proven using randomised controlled trials, including many thousands of patients. As illustrated in Figures 9.8 and 9.9, our current approach to the selection of patients for post-surgical adjuvant treatment is both intellectually impoverished and inefficient. Patients may be far better off if, rather than so much time and effort having been invested in attempting to discover new ‘cures’ for cancer, equivalent resources had been devoted to devising clinically useful tests to detect residual cancer cells persisting after apparently successful initial therapy. Had this been the case, we might now be better able to distinguish between those patients with systemic disease at presentation and those with truly localised disease.

Radiotherapy

Within a month of their discovery in 1895, x-rays were being used to treat cancer. Despite over 100 years of use and despite some outstanding clinical achievements, it is still not known how best to use radiation to treat cancer. In part this is because it is not known precisely how radiation treatment affects tumours or normal tissues. Until about 20 years ago, it was assumed that the biological effects of radiation resulted from radiation-induced damage to the DNA of dividing cells. Nowadays, it is known that, although this undoubtedly explains some of the biological effects of radiation, it does not provide a full explanation. Radiation can, both directly and indirectly, influence gene expression: over 100 radiation-inducible effects on gene expression have now been described. These changes in gene expression are responsible for a considerable proportion of the biological effects of radiation upon tumours and normal tissues. In this sense, radiotherapy is a precisely targeted form of gene therapy for cancer.

Table 9.7 Examples of malignancies that may be cured without the need for surgical excision.

Malignancy	Potentially curative treatment
Leukaemia	Chemotherapy (±radiotherapy)
Lymphoma	Chemotherapy (±radiotherapy)
Small cell lung cancer	Chemotherapy (±radiotherapy)
Tumours of childhood (rhabdomyosarcoma, Wilms’ tumour)	Chemotherapy (±radiotherapy)
Early laryngeal cancer	Radiotherapy
Advanced head and neck cancer	Chemoradiation (synchronous chemotherapy and radiotherapy)
Oesophageal cancer	Chemoradiation (synchronous chemotherapy and radiotherapy)
Squamous cell cancer of the anus	Chemoradiation (synchronous chemotherapy and radiotherapy)
Advanced cancer of the cervix	Radiotherapy (±chemotherapy)
Medulloblastoma	Radiotherapy (±chemotherapy)
Skin tumours (BCC, SCC)	Radiotherapy

BCC, basal cell carcinoma; SCC, squamous cell carcinoma.

Max Wilms, 1867–1918, Professor of Surgery, Heidelberg, Germany.
Hubert Rodney (‘Rod’) Withers, Professor of Radiation Oncology at the University of California, Los Angeles.

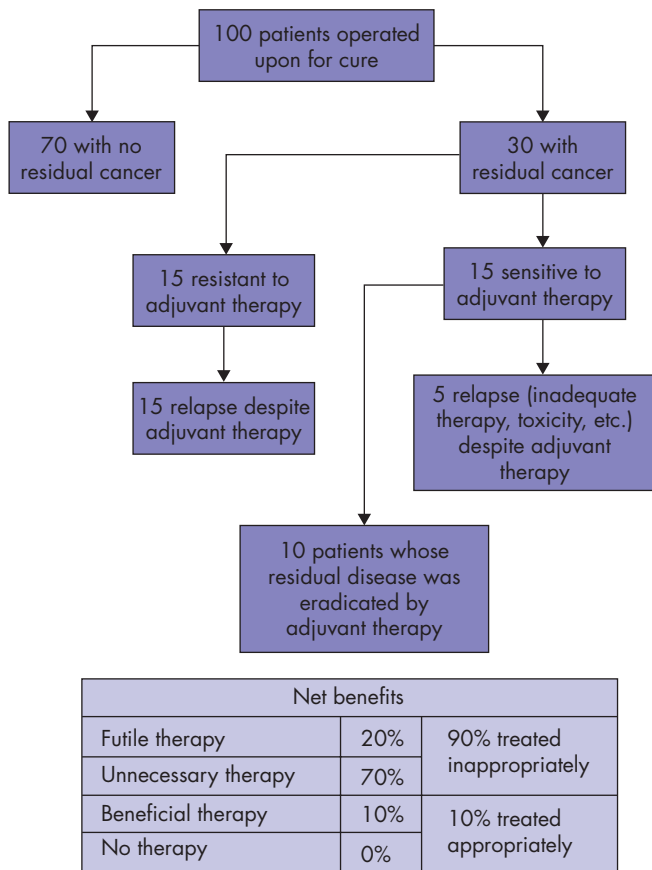

Figure 9.8 The concept of adjuvant therapy.

The practicalities of radiation therapy are reasonably straightforward: define the target to treat; design the optimal technical set up to provide uniform irradiation of that target; and choose that schedule of treatment that delivers radiation to that target so as to maximise the therapeutic ratio (Figure 9.10). One of the main problems with assessing a therapeutic ratio for a given schedule of radiation is that there is a dissociation between the acute effects on normal tissues and the late damage. The acute reaction is not a reliable guide to the adverse consequences of treatment in the longer term. As the late effects following irradiation can take over 20 years to develop, this poses an obvious difficulty: if the radiation schedule is changed, it will be known within two or three years whether or not the new schedule has improved tumour control; it may, however, be two decades before it is known, with any degree of certainty, whether the new technique is safe. Fractionated radiotherapy selectively spares late, as opposed to immediate, effects. For any given total dose, the smaller the dose per treatment (the larger the number of fractions), the less severe the late effects will be. The problem is that the greater the number of fractions of daily treatment, the longer the overall treatment time and the greater the opportunity for the tumour to proliferate during treatment. All fractionation is a compromise. Thirty years ago, Withers defined the four Rs of radiotherapy (see Summary box 9.5); subsequently, a fifth 'R' (intrinsic radiosensitivity) has been added. The clinical practice of radiation oncology operates within the limits defined by these five Rs.

Chemotherapy and biological therapies

Selective toxicity is the fundamental principle underlying the use of chemotherapy in clinical practice. The importance of the principle is further emphasised by the fact that, by itself, chemotherapy is rarely sufficient to cure cancer. Chemotherapy is often (in effect, if not intent) a palliative rather than a cura-

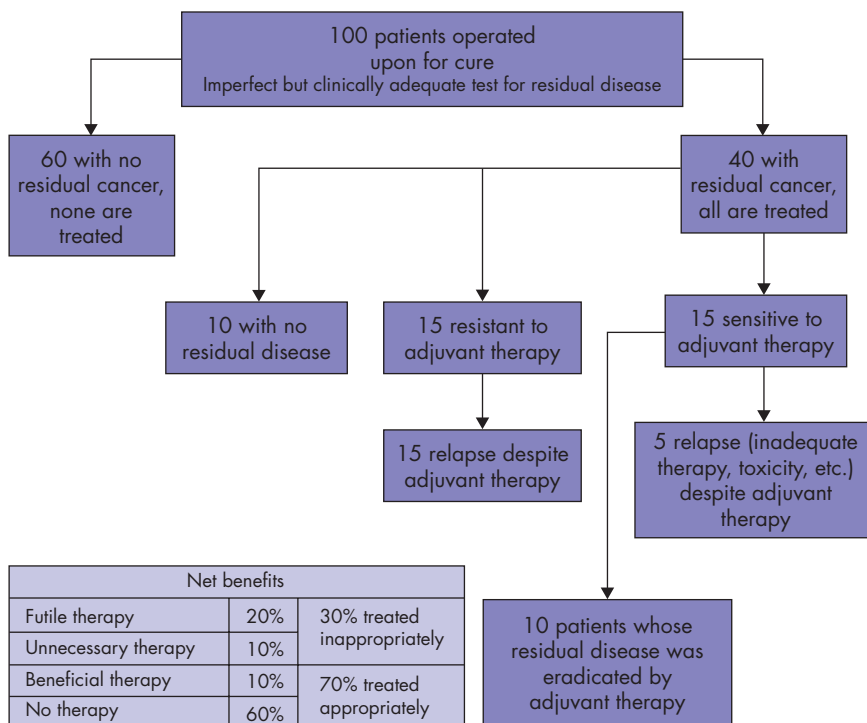

Figure 9.9 The concept of adjuvant therapy and testing for minimal residual disease.

Summary box 9.5

The five Rs of radiotherapy

- **Repair.** If given sufficient time between fractional doses of radiation, cells will repair the radiation-induced damage. Repair half-times are typically 3–6 hours. Fractionation offers a means whereby any differentials in repair capacity between tumour and normal cells may be exploited.
- **Reoxygenation.** Hypoxic cells are relatively radioresistant compared with well-oxygenated cells. Normal tissues are well oxygenated; tumours are often hypoxic. This is an obvious therapeutic disadvantage.
- **Repopulation.** As radiotherapy kills cancer cells, rapid proliferation of tumour cells is stimulated. Thus, during protracted treatment, production of cells by the tumour may equal, or even exceed, radiation-induced cell loss. It is thus better that the overall treatment time is as short as possible.
- **Redistribution.** The sensitivity of cells to radiation varies according to their position within the cell cycle. This may lead to a degree of synchronisation of cellular division within the tumour: ideally, fractions of radiotherapy should be timed to coincide with vulnerable phases of the cell cycle (late G2 and M).
- **Radiosensitivity.** Low-dose rate irradiation experiments demonstrate that cells derived from tumours differ in their intrinsic sensitivity to radiation. Some cells are so intrinsically resistant to treatment that no clinically viable schedule of radiation therapy would eliminate them. Conversely, some cells may be so sensitive that virtually any schedule would be successful – the majority of cells will lie somewhere between these extremes.

tive intervention. As such, its use should be influenced by the cardinal principle of palliative treatment: treatment aimed at relieving symptoms should not, itself, produce unacceptable symptoms. The cure of a disease should not be more grievous than its endurance. There are now over 95 different drugs licensed by the US Food and Drug Administration (FDA) for the treatment of cancer. Of these, over 65 per cent are cytotoxic drugs, 15 per cent are hormonal therapies and 15 per cent are designed to interact with specific molecular targets – so-called targeted therapies. Over 50 per cent of these agents have been licensed since 1990: in terms of potential progress, achievement over the past 15 years has equalled that of the previous 40 years. There are now many more options than there were 20 years ago and, perhaps more importantly, lessons have been learnt about how better to deploy resources. The classes of cytotoxic drugs, their mode of action and clinical indications are summarised in Table 9.8.

The newer ‘targeted’ therapies available for treating cancer present particular dilemmas. They offer modest prolongation of survival, often with minimal toxicity, but at considerable financial cost. When compared with conventional therapies, these drugs typically cost over £50 000 (US\$94 000) per quality-adjusted life-year gained and, when overall resources are limited, they may be considered unaffordable. Table 9.9 puts into context the cost-effectiveness of various clinical interventions. The current cost of targeted therapies should not obscure their importance: they represent the first attempts to translate advances in molecular biology into clinical practice.

The discoveries of the mid-twentieth century are finally bearing fruit. One feature that is emerging is the exquisite selectivity of these treatments – they will only target specific subsets of tumours. The kinase inhibitor PLX4032 will only be effective in patients with melanoma whose tumours have the V600E BRAF mutation; cetuximab is only effective in patients with colorectal cancer who have wild-type (non-mutated) ras; imatinib is particularly effective in patients with gastrointestinal stromal tumours (GIST) who have mutations in exon 11 of the *Kit* gene, patients with mutations in exon 9 may still respond to imatinib but will require higher doses, patients without mutations in *Kit* are far less likely to respond to imatinib.

The next decade will see a major shift in the medical management of cancer – from cell destruction to cellular reprogramming. As a result, cancer therapies are likely to become less acutely toxic, but the longer-term consequences of such sophisticated manipulations may be uncertain and unpredictable.

Principles of combined treatment

Cytotoxic drugs are rarely used as single agents; radiotherapy and chemotherapy are often given together. The rationale behind combination, as opposed to single-agent, drug therapy is straightforward and is analogous to that for combined antibiotic therapy: it is a strategy designed to combat drug resistance. By the time of diagnosis, many tumours will contain cancer cells that, through spontaneous mutation, have acquired resistance to cytotoxic drugs. Unlike antibiotic resistance, there is no need for previous exposure to the drug. Spontaneous mutation rates are high enough to allow chance to permit the development, and subsequent expansion, of clones of cells resistant to drugs to which they have never been exposed. If drugs were used as single agents, then the further expansion of these *de novo* resistant subclones would limit cure. The problem can be mitigated by combining drugs from the outset.

The choice of drugs for combination therapy is based upon three main principles: (1) use drugs active against the disease in question; (2) use drugs with distinct modes of action; and (3) use drugs with non-overlapping toxicities. By using drugs with different biological effects, for example by combining an anti-metabolite with an agent that actively damages DNA, it may be possible to obtain a truly synergistic effect. It is inadvisable to combine drugs with similar adverse effects: combining two highly myelosuppressive drugs may produce an unacceptably high risk of neutropenic sepsis. Where possible, combinations should be based upon a consideration of the toxicity profiles of the drugs concerned (Summary box 9.6).

Summary box 9.6

Basic principles of combined therapy

- Use effective agents
- Use agents with different modes of action (synergy)
- Use agents with non-overlapping toxicities
- Consider spatial cooperation

In considering the combination of radiotherapy and chemotherapy, radiation could be considered as just another drug.

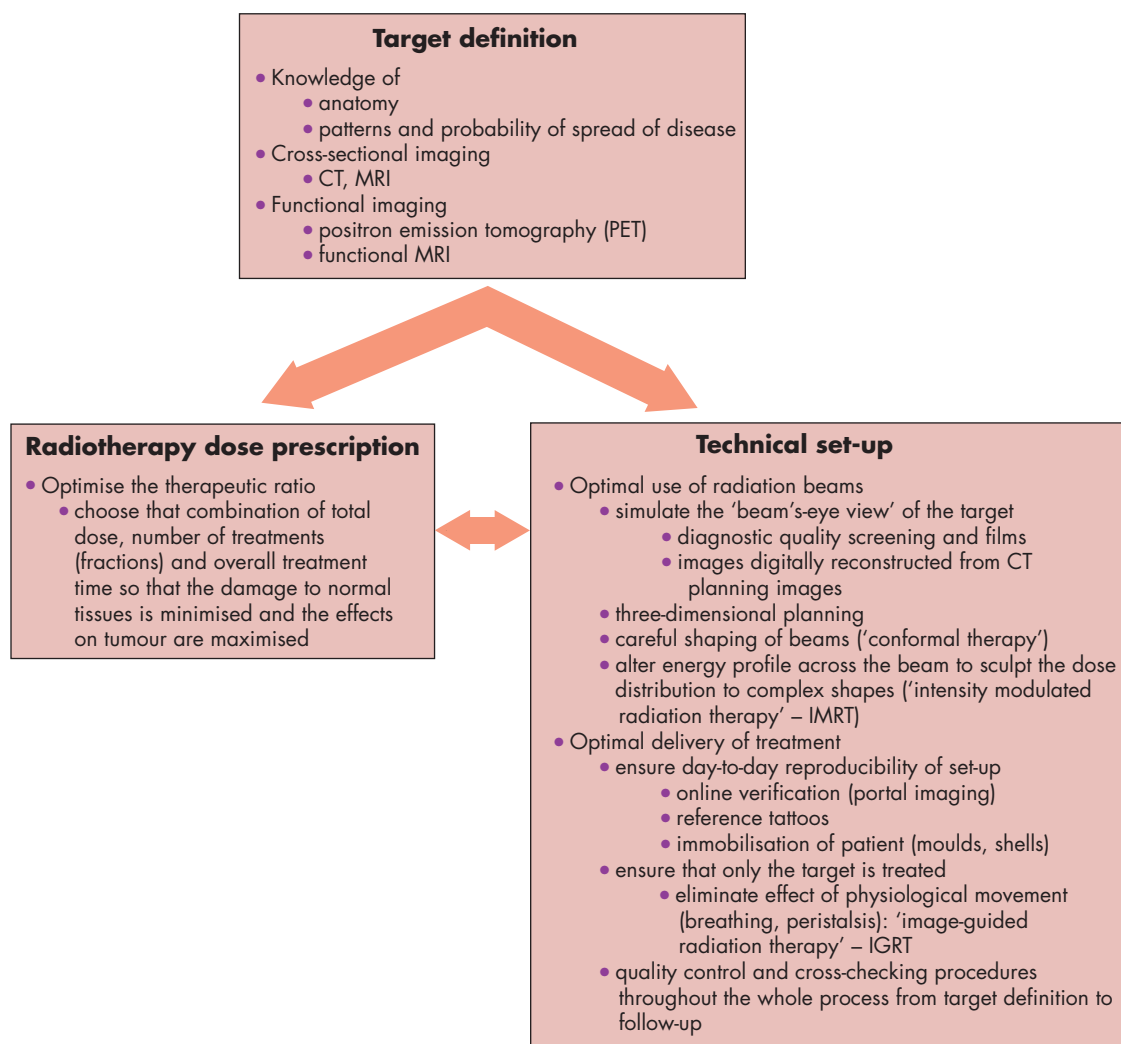

Figure 9.10 The processes involved in clinical radiotherapy. CT, computed tomography; MRI, magnetic resonance imaging.

There is, in addition to synergy and toxicity, another factor to consider in the combination of drugs and radiation – the concept of spatial cooperation. Chemotherapy is a systemic treatment; radiotherapy is not, but it is able to reach sites, such as the central nervous system and testis, which drugs may not reach effectively. This is why, for example, in patients treated primarily with chemotherapy for leukaemias, lymphomas and small cell lung cancer, prophylactic cranial irradiation is part of the treatment protocol.

Palliative therapy

The distinction between palliative and curative treatment is not always clear cut and will become increasingly blurred as professional and public attitudes towards the management of cancer change. Ten years ago, cancer was perceived as a disease that was either cured or not; patients either lived or died. There was little appreciation that, for many patients, cancer might be a chronic disease. Nowadays, many of the so-called curative treatments are simply elegant exercises in growth delay. Five-year survival is not necessarily tantamount to cure. With the development of targeted therapies that regulate, rather than eradicate, cancer,

this situation is likely to continue. The aim of treatment will be growth control rather than the extirpation of every last cancer cell. Patients will live with their cancers, perhaps for years. They will die with cancer, but not necessarily of cancer. Against this background, the distinction between curative and palliative therapy seems somewhat arbitrary, nevertheless the control and relief of symptoms is crucial to the successful management of patients with cancer. Much of the fear associated with cancer is due to past failures to control symptoms.

Patients fear the symptoms, distress and disruption associated with cancer almost as much as they fear the disease itself. Palliative treatment has as its goal the relief of symptoms. Sometimes, this will involve treating the underlying problem, as with palliative radiotherapy for bone metastases. Sometimes, it may be inappropriate to treat the cancer itself, but that does not imply that there is nothing more to be done; there may be better ways to assuage the distress and discomfort caused by the tumour. Palliative medicine in the twenty-first century is about far more than optimal control of pain: its scope is wide, its impact immense (Table 9.10). The most important factor in the successful palliative management of a patient with cancer is

Table 9.8 A summary of chemotherapeutic and biological agents currently used in cancer treatment.

Class	Examples	Putative mode of action	Tumour types that may be sensitive to drug
Drugs that interfere with mitosis	Vincristine, vinblastine	Interfere with the formation of microtubules: 'spindle poisons'	Lymphomas Leukaemias Brain tumours Sarcomas
	Taxanes: taxol, paclitaxel	Stabilise microtubules	Breast cancer Non-small cell lung cancer Ovarian cancer Prostate cancer Head and neck cancer
Drugs that interfere with DNA synthesis (anti-metabolites)	5-Fluorouracil (5-FU)	Inhibition of thymidylate synthase, false substrate for both DNA and RNA synthesis	Breast cancer Gastrointestinal cancer
	Capecitabine	Orally active prodrug that is metabolised to 5-FU. Inhibition of thymidylate synthase, false substrate for both DNA and RNA synthesis	Breast cancer Gastrointestinal cancer
	Methotrexate	Inhibition of dihydrofolate reductase	Breast cancer Bladder cancer Lymphomas Cervix cancer
	6-Mercaptopurine	Inhibits <i>de novo</i> purine synthesis	Leukaemias
	6-Thioguanine	Inhibits <i>de novo</i> purine synthesis	Leukaemias
	Cytosine arabinoside	False substrate in DNA synthesis	Leukaemias Lymphomas
	Gemcitabine	Inhibits ribonucleotide reductase	Non-small cell lung cancer Pancreatic cancer
Drugs that directly damage DNA or interfere with its function	Mitomycin C	DNA cross-linking, preferentially active at sites of low oxygen tension (a bioreductive drug)	Anal cancer Bladder cancer Gastric cancer Head and neck cancer Rectal cancer
	Cisplatin	Forms adducts between DNA strands and interferes with replication	Germ cell tumours Ovarian cancer Non-small cell lung cancer Head and neck cancer Oesophageal cancer
	Carboplatin	Forms adducts between DNA strands and interferes with replication	Germ cell tumours Ovarian cancer Non-small cell lung cancer Head and neck cancer
	Oxaliplatin	Forms adducts between DNA strands and interferes with replication	Colorectal cancer
	Doxorubicin	Intercalates between DNA strands and interferes with replication	Breast cancer Lymphomas Sarcomas Kaposi's sarcoma
	Cyclophosphamide	A prodrug converted via hepatic cytochrome p450 to phosphoramidate mustard; causes DNA crosslinks	Breast cancer Lymphomas Sarcomas
	Ifosfamide	Related to cyclophosphamide, causes DNA crosslinks	Small cell lung cancer Sarcomas
	Bleomycin	DNA strand breakage via formation of metal complex	Germ cell tumours Lymphomas

Table 9.8 A summary of chemotherapeutic and biological agents currently used in cancer treatment – *continued*.

Class	Examples	Putative mode of action	Tumour types that may be sensitive to drug
Drugs that directly damage DNA or interfere with its function – <i>continued</i>	Irinotecan	Inhibits topoisomerase 1 and thereby prevents the DNA from unwinding and repairing during replication	Colorectal cancer
	Etoposide	Inhibits topoisomerase 2; prevents the DNA from unwinding and repairing during replication	Small cell lung cancer Germ cell tumours Lymphomas
	Trabectedin	Binds to minor groove of the DNA double helix and inhibits transcription	Soft tissue sarcoma
	Dacarbazine	A nitrosourea that requires activation by hepatic cytochrome p450. Methylates guanine residues in DNA	Brain tumours Sarcoma Melanoma
	Temozolomide	A nitrosourea but, unlike dacarbazine, does not require activation by hepatic cytochrome p450. Methylates guanine residues in DNA	Glioblastoma multiforme Melanoma
	Actinomycin D	Intercalation between DNA strands, DNA strand breaks	Rhabdomyosarcoma Wilms' tumour
Hormones	Tamoxifen	Blocks oestrogen receptors	Breast cancer
	Anastrozole	An aromatase inhibitor that blocks post-menopausal (non-ovarian) oestrogen production	Breast cancer
	Exemestane	An aromatase inhibitor that blocks post-menopausal (non-ovarian) oestrogen production	Breast cancer
	Letrozole	An aromatase inhibitor that blocks post-menopausal (non-ovarian) oestrogen production	Breast cancer
	Leuprolide	Analogue of gonadotrophin-releasing hormone; continued use produces downregulation of the anterior pituitary with a consequent fall in testosterone levels	Prostate cancer
	Goserelin	Analogue of gonadotrophin-releasing hormone; continued use produces downregulation of the anterior pituitary with a consequent fall in testosterone levels	Prostate cancer
	Buserelin	Analogue of gonadotrophin-releasing hormone; continued use produces downregulation of the anterior pituitary with a consequent fall in testosterone levels	Prostate cancer
	Cabergoline	Blocks prolactin release, a long-acting dopamine agonist	Prolactin-secreting pituitary tumours
	Bromocriptine	Dopamine agonist, blocks stimulation of the anterior pituitary	Pituitary tumours
	Cyproterone acetate	Blocks the effect of androgens	Prostate cancer
	Flutamide	Blocks the effect of androgens	Prostate cancer
	Nilutamide	Blocks the effect of androgens	Prostate cancer
Inhibitors of tyrosine kinases	Bicalutamide	Blocks the effect of androgens	Prostate cancer
	Gefitinib	Inhibits EGFR tyrosine kinase	Non-small cell lung cancer

Table 9.8 A summary of chemotherapeutic and biological agents currently used in cancer treatment – *continued*.

Class	Examples	Putative mode of action	Tumour types that may be sensitive to drug
Inhibitors of tyrosine kinases – <i>continued</i>	Imatinib	Blocks the ability of mutant BCR-ABL fusion protein to bind ATP	Chronic myeloid leukaemia
		Inhibition of mutant c-KIT	Gastrointestinal stromal tumours (GIST)
	Erlotinib	Inhibits EGFR tyrosine kinase	Non-small cell lung cancer Pancreatic cancer
	Sunitinib	Promiscuous tyrosine kinase inhibitor (PDGFR, VEGFR, cKit, FLT3)	Renal cancer GIST refractory to imatinib
	Lapatinib	Inhibits tyrosine kinases associated with EGFR and HER	Breast cancer
	Crizotinib	Inhibits ALK and cMET receptor tyrosine kinases	Lung cancer, Neuroblastoma, Lymphoma
	Pazopanib	Promiscuous tyrosine kinase inhibitor – VEGFRs, PDGFR, cKit	Renal cancer
	Sorafenib	Promiscuous tyrosine kinase inhibitor (PDGFR, VEGFR, cKit, FLT3)	Renal cancer, Thyroid cancer
	Dasatinib	BCR-ABL TKI	CML
Protease inhibitors	Bortezomib	Interferes with proteasomal degradation of regulatory proteins; in particular, prevents NF kappa B from preventing apoptosis	Multiple myeloma
Differentiating agents	All <i>trans</i> -retinoic acid	Induces terminal differentiation	Acute promyelocytic leukaemia
Farnesyl transferase inhibitors	Lonafarnib	Inhibition of farnesyl transferase and consequent inactivation of <i>ras</i> -dependent signal transduction	Leukaemia
	Tipifarnib	Inhibition of farnesyl transferase and consequent inactivation of <i>ras</i> -dependent signal transduction	Acute leukaemia Myelodysplastic syndrome
BRAF kinase inhibitor	PLX4032	Blocks MAP kinase pathway	Melanoma
Histone deacetylase inhibitors (HDACi)	Vorinostat	Inhibition of HDAC	Cutaneous T-cell lymphoma
mTOR inhibitors	Temsirolimus	Inhibits mTOR	Renal cancer
	Everolimus	Inhibits mTOR	Mantle-cell lymphoma, Renal cancer
Antibodies directed to cell surface antigens	Trastuzumab	Antibody directed against HER2 receptor	Breast cancer
	Cetuximab	Antibody directed against EGFR receptor	Colorectal cancer Head and neck cancer
	Bevacizumab	Antibody directed against VEGFR	Colorectal cancer
	Rituximab	Antibody against CD20 antigen	Lymphomas
	Alemtuzumab	Antibody against CD52 antigen	Lymphomas
Inducers of apoptosis	Arsenic trioxide	Induces apoptosis by caspase inhibition, inhibition of nitric oxide	Acute promyelocytic leukaemia
Immunological mediators	Interferon alpha-2b	Activates macrophages, increases the cytotoxicity of T lymphocytes, inhibits cell division (and viral replication)	Renal carcinoma Melanoma Hairy cell leukaemia
	Thalidomide	Anti-inflammatory, stimulates T cells, anti-angiogenic	Myeloma

Table 9.8 A summary of chemotherapeutic and biological agents currently used in cancer treatment – *continued*.

Class	Examples	Putative mode of action	Tumour types that may be sensitive to drug
Immunological mediators – <i>continued</i>	Ipilimumab	A monoclonal antibody that blocks cytotoxic T-lymphocyte antigen-4 and acts as a potentiator of T-cell mediated anti-tumour responses	Melanoma

CML, chronic myeloid leukaemia; EGFR, epidermal growth factor receptor; FLT3, FMS-like tyrosine kinase; mTOR, mammalian target of rapamycin; NF, nuclear factor; PDGFR, platelet-derived growth factor receptor; TKI, tyrosine kinase inhibitor; VEGFR, vascular endothelial growth factor receptor.

Table 9.9 Estimates of cost-effectiveness for a selection of interventions

Intervention	Approximate cost per QALY in 2005 US\$
Universal antenatal screening for HIV	30 725
Laparoscopic inguinal hernia repair versus expectant management in adults with inguinal hernia	660
Annual mammograms from age 40 (cost per QALY over and above screening every 2 years aged 50 to 70)	145 160
Annual CT chest screening for lung cancer in a 60-year-old male ex-smoker versus no screening	2.6 million
Erlotinib versus usual care in the treatment of relapsed non-small cell lung cancer	75 750
Trabectedin versus best supportive care for advanced soft tissue sarcoma	96 000
Smoking cessation programme implemented at the time of surgery for lung cancer	16 400
Stroke unit care versus usual care in survivors of acute stroke	1750
Adjuvant radiotherapy for T1 breast cancer: whole breast radiotherapy (long course) versus short course partial breast irradiation	630 000
Adding trastuzumab to adjuvant chemotherapy for HER2 receptor-positive breast cancer	18 900
Adding trastuzumab to conventional chemotherapy for advanced gastric cancer	80 000
Sunitinib compared with interferon for metastatic renal cancer	52 500
¹⁸ FDG-PET-CT in the follow up of non-small cell lung cancer patients after radical radiotherapy with or without chemotherapy	91 500
Letrozole vs. tamoxifen in the first-line management of post-menopausal women with advanced breast cancer	130 000

Calculations are based on sources identified via the CEA register (<https://research.tufts-nemc.org/cear4/default.aspx>), last accessed March 21, 2011
QALY, quality adjusted life year

early referral. Transition between curative and palliative modes of management should be seamless.

End-of-life care

End-of-life care is distinct from palliative care. Patients treated palliatively may survive for many years; end-of-life care concerns the last few months of a patient's life. Many issues, such as symptom control, are common to both but there are also problems that are specific to the sense of approaching death. These may include a heightened sense of spiritual need, profound fear and the specific needs of those who are facing bereavement. The concept of the 'good death' has been embedded in many cultures over many centuries. Health-care professionals deal with many deaths and sometimes forget that the patient who hopes for a 'good death' has only one chance to get it right. This is why end-of-life care is worth considering in its own right and not as a

mere appendage to palliative care. Some of the issues unique to end-of-life care are summarised in Summary box 9.7.

Summary box 9.7

End of life issues

- Appropriateness of active intervention
- Euthanasia
- Physician-assisted suicide
- Living wills
- Bereavement
- Spirituality
- Support to allow death at home
- The problem of the medicalisation of death

Table 9.10 An outline of the domains and interventions included within palliative and supportive care.

Type of support	
Symptom assessment	Pain, anorexia, fatigue, dyspnoea, etc. Treatment-related toxicity
Quality of life assessment	
Symptom relief	Drugs Surgery Radiotherapy Complementary therapies Acupuncture Homeopathy Aromatherapy, etc.
Psychosocial interventions	Psychological support Relaxation techniques Cognitive behavioural therapy Counselling Group therapy Music therapy Emotional support
Physical and practical support	Physiotherapy Occupational therapy Speech therapy
Information and knowledge	Macmillan Maggie's centres
Nutritional support	Dietary advice Nutritional supplements
Social support	Patients Relatives and carers
Financial support	Ensure uptake of entitlements Grants from charities, e.g. Macmillan Cancer Relief
Spiritual support

LEARNING OBJECTIVES

To understand:

- The planning and conduct of audit and research
- How to write up a project
- How to review a journal article and determine its value

INTRODUCTION

It is essential for a surgeon to understand the educational and legal framework in which he or she works. The agenda for medical education and clinical governance requires surgeons to expand their skills to encompass audit and clinical research capabilities as useful tools for continued outcome measurement, service improvement and innovations for the benefit of patient care.

The aim of this chapter is to enable improvements in patient experience as a result of a successful audit cycle or by recognising the need for clinical research to determine a new and innovative way of treatment. It will also show how to keep track of personal clinical results. In addition, much clinical work is tedious and repetitive. Rigorous evaluation of even the most simple techniques and conditions can help to keep a surgeon stimulated throughout a long career and ensure good outcomes for patients, with cost benefits to the provider and a benefit to society as a whole.

Large numbers of clinical papers appear in the surgical literature every year. Many are flawed, and it is important that a surgeon has the skills to examine publications critically. The best way to develop a critical understanding of the research and audit undertaken by others is to perform studies of one's own. The hardest part of audit and research is writing it up, and the hardest article to write is the first. This chapter also contains the information required to write a surgical paper and to evaluate the publications of others.

AUDIT OR RESEARCH?

Health professionals are expected to undertake audit and service evaluation as part of quality assurance. These usually involve minimal additional risk, burden or intrusion for participants. It is important to determine at an early stage whether a project is audit or research, and sometimes that is not as easy as it seems. The decision will determine the framework in which the study is undertaken. In the UK, the National Research Ethics Service has developed helpful guidance for the definition of

research, audit, service evaluation and public health surveillance. Although developed as national guidance, it is a useful guide to decision-making generally (www.nres.npsa.nhs.uk/applications/is-your-project-research/) (Table 10.1).

AUDIT AND SERVICE EVALUATION

Clinical audit is a process used by clinicians who seek to improve patient care. The process involves comparing aspects of care (structure, process and outcome) against explicit criteria and defined standards. Keeping track of personal outcome data and contributing to a clinical database ensures that a surgeon's own performance is monitored continuously and can be compared with a national dataset to ensure compliance with agreed standards. It is also an essential component of revalidation for the individual surgeon in the UK. If the care falls short of the criteria chosen, some change in the way that care is organised should be proposed. This change may be required at one of many levels. It might be an individual who needs training or surgical equipment that needs replacing. At times, the change may need to take place at the team level. Sometimes, the only appropriate action is change at an institutional level (e.g. a new antibiotic policy), regional level (provision of a tertiary referral centre) or, indeed, national level (screening programmes and health education campaigns).

Essentially, two types of audit may be encountered: national audits (e.g. in the UK, the National Institute for Health and Clinical Excellence (NICE)) and local/hospital audits. Both are designed to improve the quality of care. In an ideal world, national audits should be driven by needs identified in local and hospital-based audits that are closest to the patient. For example, hospital topics are often identified at the departmental morbidity and mortality meetings, where issues related to patient care are discussed. The reporting process might identify a possible national issue, and a national audit could be designed to be completed by the local audit department and surgical teams. The Vascular Society of Great Britain and Ireland is working continually with all its members in an evaluation of process and outcomes for major vascular operations. This is driven by

Table 10.1 Research, audit or service evaluation?

Research	Clinical audit	Service evaluation
The attempt to derive generalisable new knowledge including studies that aim to generate hypotheses as well as studies that aim to test them	Designed and conducted to produce information to inform the delivery of best care	Designed and conducted solely to define or judge current care
Quantitative research – designed to test a hypothesis	Designed to answer the question: ‘Does this service reach a predetermined standard?’	Designed to answer the question: ‘What standard does this service achieve?’
Qualitative research – identifies/explores themes following established methodology		
Addresses clearly defined questions, aims and objectives	Measures against a standard	Measures current service without reference to a standard
Quantitative research – may involve evaluating or comparing interventions, particularly new ones	Involves an intervention in use only. (The choice of treatment is that of the clinician and patient according to guidance, professional standards and/or patient preference)	Involves an intervention in use only. (The choice of treatment is that of the clinician and patient according to guidance, professional standards and/or patient preference)
Qualitative research – usually involves studying how interventions and relationships are experienced		
Usually involves collecting data that are additional to those for routine care, but may include data collected routinely. May involve treatments, samples or investigations additional to routine care	Usually involves analysis of existing data, but may include administration of simple interviews or questionnaires	Usually involves analysis of existing data, but may include administration of simple interviews or questionnaires
Quantitative research – study design may involve allocating patients to intervention groups	No allocation to interventions: the health professional and patient have chosen intervention before clinical audit	No allocation to intervention: the health professional and patient have chosen intervention before service evaluation
Qualitative research uses a clearly defined sampling framework underpinned by conceptual or theoretical justifications		
May involve randomisation	No randomisation	No randomisation

Although any of the above may raise ethical issues, under current guidance, research requires ethics committee review, whereas audit and service evaluation do not. Advice (in the UK) from National Research Ethics Service (www.nres.npsa.nhs.uk/). Based on information by the National Research Ethics Service.

a Quality Improvement Programme (www.aaqip.org.uk) that was originally designed to feedback outcomes in aortic surgery to individual units, but which has been extended to include other high risk vascular procedures, such as carotid endarterectomy and leg amputation. Issues that are of local importance are addressed within the local hospital or hospital trusts (in the UK).

Audits are formal processes that require a structure. The following steps are essential to establish an audit cycle:

- 1 Define the audit question in a multidisciplinary team.
- 2 Identify the body of evidence and current standards.
- 3 Design the audit to measure performance against agreed standards based on strong evidence. Seek appropriate advice (local audit department in UK).
- 4 Measure over an agreed interval.
- 5 Analyse results and compare performance against agreed standards.
- 6 Undertake gap analysis:

- a. If all standards are reached, reaudit after an agreed interval.
- b. If there is a need for improvement, identify possible interventions such as training, and agree with the involved parties.

7 Reaudit.

Research study

During the design of the audit project, it might become apparent that there is a limited body of evidence available. In this case, the study should be structured as a research proposal. Research is designed to generate new knowledge and might involve testing a new treatment or regimen.

IDENTIFYING A RESEARCH TOPIC

The hardest part of research is to come up with a good idea. Once an idea has been formed, or a question asked, it needs

to be transformed into a hypothesis. It is helpful to approach surgeons who regularly publish articles and who have a special interest in the surgical area being considered. As ideas are suggested, keep thinking whether the question posed really matters. Spend some time refining the question because this is probably the most important part of the study. Choosing the wrong topic at this stage can lead to many wasted hours. Once a topic has been identified, do not rush into the study. It is worth spending considerable time investigating the subject in question. The worst possible outcome is to find at the end of a long arduous study that the research has already been done.

First port of call for information is the internet (with assistance as needed from a medical library). Look for current articles about the proposed research; review articles and meta-analyses can be particularly helpful. At this stage, most clinicians go to an electronic library and perform a database search. It is very important to learn how to do an accurate and efficient search as early as possible. Details are beyond the scope of this chapter, but most librarians will help out if a little interest and enthusiasm is shown. Current techniques involve searching on Medline or other collected databases such as Google Scholar, but as electronic information advances and the web becomes more user friendly, new search strategies may emerge. Collections of reviews are becoming available – the Cochrane Collaboration brings together evidence-based medical information and is available in most libraries (Table 10.2).

Once a stack of articles on the subject has been obtained, it is important that these are carefully perused. Don't just read the abstract on Medline! If the proposed project is still looking good after some thorough reading, it is worth further discussion with colleagues who have written a paper on a similar subject. All scientists are flattered by interest in their work. Now it should be possible to start to plan the research project.

PROJECT DESIGN

During the first phase, it is important to keep in the mind some important questions (Summary box 10.1).

Summary box 10.1

Questions to answer before undertaking research

- Why do the study?
- Will it answer a useful question?
- Is it practical?
- Can it be accomplished in the available time and with the available resources?
- What findings are expected?
- What are the research governance requirements?
- What are the ethical issues?
- What impact could it have?

Time spent carefully designing a potential project is never wasted. There are many different types of scientific study. The design used depends on the study. A randomised controlled trial (RCT) is regarded as one of the best methods of scientific research, however that much surgical practice has been advanced through other different types of study such as those listed in Table 10.3. For example, testing a new type of operation often requires a pilot study to assess feasibility that is then followed by a formal RCT. The introduction of innovative surgical techniques may require novel handling, and recommendations have been made by the IDEAL collaborators (see Further reading).

Research can be qualitative or quantitative. Quantitative

Cochrane Collaboration and Library (www.cochrane.co.uk)	International network of people helping healthcare providers, policy makers, patients, their advocates and carers, make well-informed decisions about human health care	Preparing, updating and promoting the accessibility of Cochrane Reviews published online in <i>The Cochrane Library</i>	Internet

^aLicensed to many organisations who provide their own interface. Main providers offering a pay-as-you-go service can be found: www.ovid.com or www.silverplatter.com.

The Cochrane Collaboration was formed in 1993 and named after Archibald Leman Cochrane, 1909–1988, Director of the Medical Research Council Epidemiology Unit, Cardiff, and later the first President of the Faculty of Community Medicine (now the Faculty of Public Health) of the Royal College of Physicians of London, UK.

Table 10.3 Types of study.

Type of study	Definition
Observational	Evaluation of condition or treatment in a defined population Retrospective: analysing past events Prospective: collecting data contemporaneously
Case-control	Series of patients with a particular disease or condition compared with matched control patients
Cross-sectional	Measurements made on a single occasion, not looking at the whole population, but selecting a small similar group and expanding results
Longitudinal	Measurements are taken over a period of time, not looking at the whole population, but selecting a small similar group and expanding results
Experimental	Two or more treatments are compared. Allocation to treatment groups is under the control of the researcher
Randomised	Two randomly allocated treatments
Randomised controlled	Includes a control group with standard treatment

research allows hard facts to speak for themselves. A medical condition is analysed systematically using hard, objective end points such as death or major complications, which should be clearly defined. In qualitative research, data often come from patient narratives, and the psychosocial impact of the disease and its treatment are analysed, for example narratives from patients with breast cancer. These kinds of data are often collected using quality-of-life measurements. A variety of different quality-of-life questionnaires exist to suit several different clinical situations. Much of the best research is both quantitative and qualitative.

Research should be focused according to national (and international) strategies. As finances for health care are always limited, it is important to consider including a cost-benefit analysis in any major area of research so that the value of the proposed intervention or change in treatment can be assessed. 'Best Research for Best Health' provided a National Health Service (NHS) research strategy for England and Wales that has resulted in the successful set up of the National Institute for Health Research (NIHR). NIHR provides the framework through which the Department of Health maintains and manages the research, research staff and research infrastructure of the NHS in England (www.nihr.ac.uk/Pages/default.aspx).

Sample size

Calculating the number of patients required to perform a satisfactory investigation is an important prerequisite to the study. An incorrect sample size is probably the most frequent reason for research being invalid. Often, surgical trials are marred by the possibility of error caused by the inadequate number of patients investigated.

- **Type I error.** Benefit is perceived when really there is none (false positive)
- **Type II error.** Benefit is missed when it was there to be found (false negative)

Calculating the number of patients required in the study can overcome this bias. Unfortunately, it often reveals that a larger

number of patients is needed for the study than can possibly be obtained from available resources. This often means expanding enrolment by using a multicentre study. There is no point in embarking on a trial if it will never be possible to recruit an adequate population to answer the research question. More patients will need to be randomised than the final sample size to take into account patients who die, drop out or are lost to follow up.

The following is an example calculation for a study to recruit patients into two groups. In order to calculate a sample size, it is common practice to set the level of power for the study at 80 per cent with a 5 per cent significance level. This means that, if there is a difference between study groups, there is an 80 per cent chance of detecting it. Based on previous studies, realistic expectations of differences between groups should be used to calculate the sample size. The formula below uses the figures of a reduction in event rate from 30 to 10 per cent (e.g. a new treatment expected to reduce the complication rate such as wound infection from 30 per cent = r to 10 per cent = s).

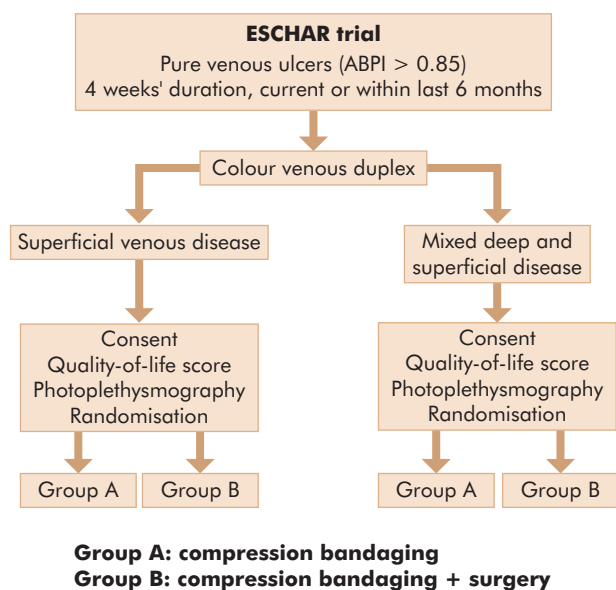

$$8 \times \frac{[r(100 - r) + s(100 - s)]}{(r - s)^2}$$

$$\text{e.g. } 8 \times \frac{[30(100 - 30) + 10(100 - 10)]}{(30 - 10)^2}$$

$$= 60 \text{ needed in each group}$$

Eliminating bias

It is important to imagine how a study could be invalidated by thinking of things that could go wrong. One way to eliminate any bias inherent in the data collection is to have observers or recorders who do not know which treatment has been used (blinded observer). It might also be possible to ensure that the patient is unaware of the treatment allocation (single blind). In the best randomised studies, neither patient nor researcher is aware of which therapy has been used until after the study has finished (double blind). Randomised trials are essential for testing new drugs. In practice, however, in some surgical trials, randomisation may not be possible or ethical.

Outcomes

- Ulcer healing and recurrence rates
- Venous function tests
- Quality of life and cost-benefit

Figure 10.1 ESCHAR trial: completed in Gloucestershire, UK (Gohel MS *et al.* *British Journal of Surgery* 2005; **92**: 291–7. Copyright British Journal of Surgery Society Ltd. Permission is granted by John Wiley & Sons Ltd on behalf of the BJSS Ltd.) ABPI, ankle-brachial pressure index.

Study protocol

Now that the question to pose has been decided, and it has been checked that sufficient patients will be available to enrol into the study, it is time to prepare the detail of the trial. At this stage, a study protocol should be constructed to define the research strategy. It should contain a paragraph on the background of the proposed study, the aims and objectives, a clear methodology, definitions of population and sample sizes and methods of proposed analysis. It should include the patient numbers, inclusion and exclusion criteria and the timescale for the work. At this stage, it is useful to construct a flow diagram giving a clear summary of the research protocol and its requirements (Figure 10.1). It is helpful to imagine the paper that will be written about the study, before it is performed. This may prevent errors in data collection.

When a study is planned, sufficient time should be reserved at the beginning for fund-raising and obtaining ethical, regulatory and NHS R&D or other management approvals. Time for data analysis and preparation of publication needs to be included in funding applications. The cost of any non-routine investigations and extra treatments should be identified and covered by the research grant.

A data collection form should be designed or a computer collection package developed. If data are collected on computer, appropriate safeguards for privacy and confidentiality will be necessary to comply with legislation on data protection. Any form of data collection needs to be quality assured. The quality assurance process will include training, as well as monitoring and checking a certain sample of the data. At the end of data collection and analysis, a final database with all data should be locked

and kept for future reference in a safe location. A data archiving policy via a data controller needs to be in place.

It is important to ensure the cooperation of any other specialties or clinicians who will be involved in the study and to agree on the sharing of responsibility for the trial. This will also help to prevent disagreement about who takes the credit once a study is ready for presentation and publication.

Regulatory framework

In the UK, the implementation of the research governance framework by the Department of Health provides a framework that enhances the integrity of your study and includes requirements for sponsorship by an institution to ensure the following: peer review, independent ethics review, compliance with data protection principles, financial probity, dissemination and management of intellectual property.

Peer review

Once the protocol is finalised, formal peer review is needed. In the UK, evidence of peer review will be needed before submitting an application to an ethics committee and for hospital trust approval.

- If the research is part of a university course, the university should undertake this review.
- Surgeons working for the NHS can arrange their own peer review by experts who are not connected with the study. Alternatively, most Research and Development Support Units (NHS) will give guidance through the review process.
- Funders of research will usually undertake their own independent peer review. There is usually feedback from this process that often gives valuable advice about the study.

Ethics

In the first instance, common sense is the best guide to whether or not a study is ethical. It is still important to seek advice from an ethics committee whenever research is contemplated.

In the UK, the requirement is that a NHS Research Ethics Committee (NHS REC) provides an independent ethical review of all health and social care research if it involves patients, carers, NHS staff and NHS premises (www.dh.gov.uk/assetRoot/04/12/24/27/04122427.pdf). In addition, the NHS REC provides an ethical review for studies that involve relevant material in line with the Human Tissue Act (www.legislation.gov.uk/ukpga/2004/30/contents) and studies that might involve participants that might lack capacity in line with the Mental Capacity Act (www.legislation.gov.uk/ukpga/2005/9/contents).

The application for NHS REC review should be made using the Integrated Research Administration System (IRAS) (www.myresearchproject.org.uk/SignIn.aspx). IRAS is a single system for applying for the permissions and approvals for health and social care/community care research in the UK. It enables regulatory and governance requirements to be met while entering the information about the project once, instead of duplicating information in separate application forms for:

- Administration of Radioactive Substances Advisory Committee (ARSAC)
- Gene Therapy Advisory Committee (GTAC)
- Medicines and Healthcare products Regulatory Agency (MHRA)
- Ministry of Justice

- NHS/HSC R&D offices
- NRES/NHS/HSC Research Ethics Committees
- National Information Governance Board (NIGB)
- National Offender Management Service (NOMS)
- Social Care Research Ethics Committee.

Once all relevant forms and associated study documentation have been completed, guidance provided by the National Research Ethics Service should be followed for submission of the request for ethical review (www.nres.npsa.nhs.uk/applications/).

If the study does not require review by an NHS REC, the need for an independent ethical review should still be considered. Universities have developed their own ethical review infrastructure and this will be institute and location specific. For collaborative research, local ethical review should be obtained where possible and developing a local ethics infrastructure should be considered if it does not already exist. Duplication of ethical review should be avoided where possible.

Ethics committees prefer to see fully developed trial protocols, but it is often possible to get some preliminary advice from the committee chair. Ethics committee forms may seem long and detailed, but it is important that these are filled in correctly. All dealings with ethics committees should be intelligent and courteous. It is important to attend the meeting at which the study will be discussed, if invited, as it provides a forum for direct communication in relation to the study. It can save time as possible concerns of the ethics committee can be addressed immediately, avoiding lengthy correspondence.

Regulatory approvals

In the case of clinical trials, the European Union Clinical Trial Directive applies and is regulated by the Medicines and Health Care products Regulatory Agency (MHRA) in the UK (www.mhra.gov.uk/Howweregulate/index.htm). A clinical trial should be registered with the European Clinical Trials Database (www.eudract.emea.europa.eu) or one of the other free databases (www.clinicaltrials.gov) before applying to the MHRA for a Clinical Trial Authorisation. This can be a complicated and trying process, and support should be sought from the investigators' employing institution. Editors of the major surgical journals now agree that all clinical trials should have been registered before an article relating to a trial can be published. All studies undertaken in the NHS will need NHS R&D management approval. Studies involving animals require approval from statutory licensing authorities. Do not embark on the study until the correct approval has been granted.

STATISTICAL ANALYSIS

Both audit and research commonly require statistical analysis. Many surgeons find the statistical analysis of a project the most difficult part. It is also the most commonly criticised part of papers written by clinicians.

There are many useful books about statistics which can be consulted (see Further reading); if in any doubt, a statistician will be pleased to give assistance. Statisticians like to be consulted before research or audit has been conducted rather than being presented with the data at the end; they often give helpful advice over study design.

The following terms are frequently used when summarising statistical data:

- **Mean:** the result of dividing the total by the number of observations (the average);
- **Median:** the middle value with equal numbers of observations above and below – used for numerical or ranked data;
- **Mode:** the value with the highest frequency observed – used for nominal data collection;
- **Range:** the largest to the smallest value.

The most important decision for analysis is whether the distribution of results is normal, i.e. parametric or non-parametric. Normally distributed data have a symmetrical, bell-shaped curve, and the mean, median and mode all lie at the same value. The type of data collected determines which statistical test should be used.

- 1 Numerical and normally distributed (e.g. blood pressure) – use unpaired *t*-test to compare two groups, or paired *t*-test to assess whether a variable has changed between two time points.
- 2 Numerical but not normally distributed (e.g. tumour size) – use Mann–Whitney *U*-test to compare two groups, or a Wilcoxon signed rank test to assess whether a variable has increased/stayed the same/decreased between two time points.
- 3 Categorical (e.g. admitted or not admitted to an intensive care unit) – can use chi-squared test to compare two groups.

(Please note: the use of any other tests may benefit from professional advice.)

Confidence intervals are the best guide to the possible range in which the true differences are likely to lie. A confidence interval that includes zero usually implies a lack of statistical significance.

Scientists usually employ probability (*p*-values) to describe statistical chance. A *p*-value <0.05 is commonly taken to imply a true difference. It is important not to forget that *p* = 0.05 simply means there is only a 1:20 chance that the differences between the variables would have happened by chance when in fact there is no real difference. If enough variables are examined in any study, significant differences will occur simply by chance. Trials with multiple end points or variables require more sophisticated analysis to determine the significance of individual risk factors. Univariable or multivariable logistic regression analysis techniques may be appropriate.

Statistics simply deal with the chance that observations between populations are different and should be treated with caution. Clinical results should show clear differences. If statistics are required to demonstrate differences between results, it is possible that they are unlikely to have major clinical significance.

Computer software packages available

Statistical computer packages offer a quick way of analysing descriptive statistics, such as mean, median and range, as well as the most commonly used statistical tests, such as the chi-squared test. Various packages are available commercially and are useful tools in data analysis.

ANALYSING A SCIENTIFIC ARTICLE

The simplest way to analyse an article from a scientific journal is to look at the checklist of requirements for good scientific research. A group of scientists and editors developed

Table 10.4 Checklist for authors.

Heading	Sub-heading	Descriptor
Title		Identify as randomised trial
Abstract		Structured format
Introduction		Prospectively defined hypotheses, clinical objective
Methods	Protocol	Study population
		Intervention, timing
		Primary and secondary outcome
		Statistical rationale
	Assignment	Stopping rules
		Unit of randomisation
		Method: allocation schedule
	Masking (blinding)	
Results	Participant flow and follow up	Trial profile, flow diagram
	Analysis	Estimated effect of intervention
		Summary data with appropriate inferential statistics
		Protocol deviation
Comment		Specific interpretation of study
		Sources of bias
		External validity
		General interpretation

From the CONSORT statement: *Journal of the American Medical Association* 1996; **276**: 637–9.

the CONSORT (Consolidated Standards of Reporting Trials) statement to improve the quality of reporting of RCTs. Looking in detail at the study design is often the best way of deciding whether a trial is any good. The CONSORT document includes a checklist for the conduct of good randomised trials (Table 10.4). Often, clinicians overlook biases that others find obvious to detect, which can have a profound influence on the outcome of any study. Even the randomised design does not always guarantee quality, and a core component of systematic review is the grading of trial quality; several scoring systems have been developed, e.g. Jadad Score. Recent guidelines have been published formalising the methods of systematic review and meta-analysis (PRISMA guidelines), and most surgical journals will now only accept articles that follow the rules.

PRESENTING AND PUBLISHING AN ARTICLE

There is no point in conducting a research or audit project and then leaving the results unreported. Even when results are negative, they are worth distributing; no project if properly conducted is worthless. Under-reporting of negative outcomes causes a systematic bias in the literature in favour of positive trials. Most studies do not provide dramatic results, and few surgeons publish seminal articles.

The key to both presentation and publication is to decide

on the message, and then aim for an appropriate forum. Large important randomised studies or national audits merit presentation at national meetings and publication in international journals. Small observational studies and audits are more often accepted for presentation at regional or hospital meetings and for publication in smaller specialist journals. Help and advice from clinicians familiar with presentation and publication are invaluable at this stage. The most important piece of advice is to follow the instructions for journal submission accurately. Most international meetings will accept presentations eagerly (especially by poster) as this increases the attendance at a conference.

Most surgeons publish research in peer-reviewed journals. The work that is submitted is checked anonymously by other surgeons before publication. If in doubt about whether to submit to a journal, many editors will give advice about the suitability of an article for submission to their journal.

Convention dictates that articles are submitted in IMRAD form (introduction, methods, results and discussion). Increasingly, electronic publication and the internet may change the face of scientific publication and, in the next decade, these restrictions on style may disappear. For now, the IMRAD format remains inviolable. The length of an article is important: a paper should be as long as the size of the message. Readers of large randomised multicentre trials wish to know as much detail about the study as possible; reports on small negative trials should be brief.

- **Introduction.** This should always be short. A brief background of the study should be presented and then the aims of the trial or audit outlined.
- **Methods.** The methodology and study design should be given in detail. It is important to own up to any biases. Any new techniques or investigations should be detailed in full; if they are common practice or have been described elsewhere, this should be referenced instead of described.
- **Results.** Results are almost always best shown diagrammatically using tables and figures if possible. Results shown in the form of a diagram need not then be duplicated in the text.
- **Discussion.** It is important not to repeat the introduction or reiterate the results in this section. The study should be interpreted intelligently, and any suggestions for future studies or changes in management should be made. It is important not to indulge in flights of fantasy or wild imagination about future possibilities; most journal editors will delete these. Recently, a standard format for the discussion section has been promoted, and journals such as the *British Medical Journal* are keen that authors use it.
- **References.** This section should include all relevant papers recording previous studies on the subject in question. The number should reflect the size of the message and the importance of the work. The reference section does not usually have to be exhaustive, but should include up-to-date articles. Remember to present the references in the style of the journal of submission.

EVIDENCE-BASED SURGERY

Surgical practice has been considered an art: ask 50 surgeons how to manage a patient and one will probably get 50 different answers. There is so much clinical information available that no surgeon can know it all. Evidence-based surgery is a move to find the best ways of managing patients using clinical evidence from collected studies. It was estimated that sufficient evidence to justify routine myocardial thrombolysis for heart attacks was available years before the randomised clinical studies that finally made it clinically acceptable. No-one had gathered all the available information together. Centres such as the Cochrane Collaboration have been collecting randomised trials and reviews to provide up-to-date information for clinicians. The Cochrane Library presently includes a database of systematic reviews, reviews of surgical effectiveness and a register of controlled trials. The *British Journal of Surgery* has been collecting surgical randomised trials on its website archive for ten years (www.bjs.co.uk). There are now almost 1500 annotated references that can be a valuable resource for scientific authors. As evidence accumulates, it is expected that this will gradually smooth out the differences between clinicians as the best way of managing patients becomes more obvious. Collecting published evidence together and analysing it often requires reviews of multiple randomised trials. These meta-analyses involve complex statistical analyses designed to interpret multiple findings and synthesise the results of multiple studies. There exist standard formats for the presentation of meta-analyses described in the PRISMA guidelines (produced after a conference that was convened to address standards for improving the quality of reporting of meta-analysis of clinical RCTs).

Surgical ethics and law

LEARNING OBJECTIVES

To understand:

- The importance of autonomy in good surgical practice
- The moral and legal boundaries and practical difficulties of informed consent
- Good practice in making decisions about the withdrawal of life-sustaining treatment
- The importance and boundaries of confidentiality in surgical practice
- The importance of appropriate regulation in surgical research
- The importance of rigorous training and maintenance of good practice standards

INTRODUCTION

This chapter incorporates references to English common and statute law. Nevertheless, these legal and ethical principles have much in common with many other jurisdictions across the world.

Surgery, ethics and law go hand in hand. In any other arena of public or private life, if someone deliberately cuts another person, draws blood, causes pain, leaves scars and disrupts everyday activity, then the likely result will be a criminal charge. If the person dies as a result, the charge could be manslaughter or even murder. Self-evidently, the difference between the criminal and the surgeon is that their intentions differ. While a criminal intentionally (or recklessly) inflicts harm, the surgeon's intention is limited to the treatment of illness. Any harm that ensues is either unintentional, or is necessary (such as an incision), to facilitate treatment.

Patients submit to surgery because they trust their surgeons. What should consent entail in practice and what should surgeons do when patients need help but are unable or unwilling to agree to it? When patients do consent to treatment, surgeons are provided with a wide discretion. The end result may be cure, but disfigurement, disability and death may also result. How should such surgical 'power' be regulated to reinforce the trust of patients; and to ensure that surgeons practise to an acceptable professional standard? Are there circumstances, in the public interest, in which it is acceptable to sacrifice the trust of individual patients through revealing information that was communicated in what patients believed to be conditions of strict privacy?

These questions about what constitutes good professional practice concern medical ethics and law relating to consent, confidentiality, and the underlying concept of personal autonomy.

In addition, these principles need to be applied to surgical activities, including professional matters relating to governance,

regulation and the process of revalidation, in its different guises around the world. Surgical training is starting to embrace the 'basic science' of surgical law, to offer surgeons assistance in the resolution of such ethical dilemmas. This chapter is evidence of that process.

RESPECT FOR AUTONOMY

Surgeons have a duty of care towards their human patients which goes beyond just protecting their life and health. Their additional duty of care is to respect the autonomy of their patients and their ability to make choices about their treatments, and to evaluate potential outcomes in light of other life plans. Such respect is particularly important for surgeons because, without it, the trust between them and their patients may be compromised, along with the success of the surgical care provided. We are careful enough in everyday life about whom we allow to touch us; and to see us unclothed. It is hardly surprising that many people feel strongly about exercising the same control over a potentially hazardous activity, such as surgery.

For all these reasons, there is a wide moral and legal consensus that patients have the right to exercise choice over their surgical care. In this context, a right should be interpreted as a claim that can be made on the surgeon. The surgeon, therefore, accepts the strict duty to respect the patient's choice, regardless of personal preferences. Thus, to the degree that patients have a right to make choices about proposed surgical treatment, it then follows that they should be allowed to refuse treatments that they do not want, even when surgeons think that they are wrong. For example, patients can even refuse surgical treatment that will save their lives, either at present or in the future, through the formulation of advance decisions specifying the types of life-saving treatments that they do not wish to have, notwithstanding that they may later become incompetent to refuse them.

INFORMED CONSENT

In surgical practice, respect for autonomy translates into the clinical duty to obtain informed consent before the commencement of treatment.

It is easy to underestimate the gap in understanding between a surgeon and his or her patient. How many patients would recognise that unilateral eye surgery might lead to contralateral blindness? The risks and side effects of many operations are not intuitive, and the surgeon is not in the position to guess how the patient's plans for employment, leisure and family life may be inadvertently affected by a foreseeable complication. A budding Olympic gymnast might choose to forgo surgery on a quiescent posterior triangle lesion if they knew the potential consequences of division of the accessory nerve. That is why patients need to be informed, beforehand, so they can choose whether to take the risk.

To establish valid consent to treatment, patients need to be given appropriate and accurate information. In England and Wales, the Department of Health's Reference Guide to Consent should be consulted.

Such information should include:

- the condition and the reasons why it warrants surgery;
- the type of surgery proposed and how it might correct the condition;
- the anticipated prognosis and expected side effects of the proposed surgery;
- the unexpected hazards of the proposed surgery;
- any alternative and potentially successful treatments other than the proposed surgery;
- the consequences of no treatment at all.

With such information, patients can link their clinical prospects with the management of other aspects of their life and the lives of others for whom they may be morally and/or professionally responsible. Good professional practice dictates that obtaining informed consent should occur in circumstances that are designed to maximise the chances of patients understanding what is said about their condition and proposed treatment, as well as giving them an opportunity to ask questions and express anxieties.

Where possible:

- a quiet venue for discussion should be found;
- written material in the patient's preferred language should be provided to supplement verbal communication, together with diagrams where appropriate;
- patients should be given time and help to come to their own decision;
- the person obtaining the consent should ideally be the surgeon who will carry out the treatment. It should not be – as is sometimes the case – a junior member of staff who has never conducted such a procedure and thus may not have enough understanding to counsel the patient properly.

Good communication skills go hand in hand with properly obtaining informed consent for surgery. It is not good enough just to go through the motions of providing patients with the information required for considered choice. Attention must be paid to:

- whether or not the patient has understood what has been stated;

- avoiding overly technical language in descriptions and explanations;
- the provision of translators for patients whose first language is not English;
- asking patients if they have further questions.

When there is any doubt about their understanding, surgeons should ask patients questions about what has supposedly been communicated to see if they can explain the information in question for themselves.

Surgeons have a legal, as well as a moral, obligation to obtain consent for treatment based on appropriate disclosure. Failure to do so could result in one of two civil proceedings, assuming the absence of criminal intent. First, in law, intentionally to touch another person without their consent is a battery, remembering that we are usually touched by strangers as a consequence of accidental contact. Surgeons have a legal obligation to give the conscious and competent patient sufficient information 'in broad terms' about the surgical treatment being proposed and why. If the patient agrees to proceed, no other treatment should ordinarily be administered without further explicit consent.

Negligence is the second legal action that might be brought against a surgeon for not obtaining appropriate consent to treatment. Patients may have been given enough information about what is surgically proposed to agree to be touched in the ways suggested. However, surgeons may still be in breach of their professional duty if they do not provide sufficient information about the risks that patients will encounter through such treatment. Although standards of how much information should be provided about risks vary between nations, as a matter of good practice, surgeons should inform patients of the hazards that any reasonable person in the position of the patient would wish to know. In English law, this level of disclosure has been most recently reviewed in the case of *Chester v. Afshar*.

Finally, surgeons now understand that, when they obtain consent to proceed with treatment, then patients are expected to sign a consent form of some kind. The detail of such forms can differ, but they often contain very little of the information supposedly communicated to the patient who signed it. Partly for this reason, the process of formally obtaining consent can become overly focused on obtaining the signature of patients rather than ensuring that appropriate types and amounts of information have been provided, and have been understood.

Both professionally and legally, it is important for surgeons to understand that a signed consent form is not proof that valid consent has been properly obtained. It is simply a piece of evidence that consent may have been attempted. Even when they have provided their signature, patients can and do deny that appropriate information has been communicated or that the communication was effective. Surgeons are therefore well advised to make brief notes of what they have said to patients about their proposed treatments, especially information about significant risks. These notes should be placed in the patient's clinical record. In addition, information sheets describing the generic risks, benefits and complications associated with the proposed procedure can be provided.

PRACTICAL APPLICATION

Thus far, we have examined the moral and legal reasons why the duty of surgeons to respect the autonomy of patients translates

into the specific responsibility to obtain informed consent to treatment. For consent to be valid, patients must:

- be competent to give it – be able to understand, remember and deliberate about whatever information is provided to them about treatment choices, and to communicate those choices;
- not be coerced into decisions that reflect the preferences of others rather than themselves;
- be given sufficient information for these choices to be based on an accurate understanding of reasons for and against proceeding with specific treatments.

Surgical care would grind to a halt if it were always necessary to obtain explicit informed consent every time a patient is touched in the context of their care. Fortunately, it is an elementary step merely to ask the patient whether they mind being examined – the usual response will be acceptance. This simple transaction illustrates that the legal and ethical ‘rules’ that govern a surgeon are often no more than an expression of good clinical practice; in this case, politeness.

Some patients will not be able to give consent because of temporary incapacity. This may result from their presenting illness or intoxication; or an unanticipated situation may be encountered midway through a general anaesthetic. The moral and legal rules that govern such situations are clear. The doctrine of medical necessity enables the surgeon, in an emergency, to save life and prevent permanent disability, operating without consent. This is employed daily, where unconscious emergency patients undergo surgery to save ‘life and limb’. No consent has been provided, and none is required, providing the treatment is in the patient’s best interests.

However, if the patient has made a legally valid advance decision refusing treatment of the specific kind required, their decision must be honoured, providing it is applicable to the current clinical situation. Where possible, surgery on patients who are temporarily incapacitated should be postponed until their capacity is restored, and they are able to give informed consent or refusal for themselves.

Surgeons must take care to respect the distinction between procedures that are necessary to prevent death or irremediable harm, and those that are done merely out of convenience. If the patient consents only to a dilatation and curettage, do not consider performing an additional hysterectomy ‘in her best interests’, simply because she is anaesthetised.

Consent may be made impossible by incompetence of other kinds. In the case of children, parents or someone with parental responsibility are ordinarily required to provide consent on their behalf. This said, surgeons should:

- take care to explain to children what is being surgically proposed and why;
- always consult with children about their response;
- where possible, take the child’s views into account and note that even young children can be competent to consent to treatment provided that they too can understand, remember, deliberate about and believe information relevant to their clinical condition.

When such *Gillick* competence is present, under English law, children can provide their own consent to surgical care, although they cannot unconditionally refuse it until they are 18 years old. These provisions illustrate the importance of respecting as much

autonomy as is present among child patients and remembering that, for the purposes of consent to medical treatment, they may be just as autonomous as adults.

If competence is severely compromised by psychiatric illness or mental handicap, other moral and legal provisions hold. If patients lack the autonomy to choose how to protect themselves as regards the consequences of their illness then others charged with protecting them must assume the responsibility. Yet care must be taken not to abuse this duty. Even when such patients have been legally detained for compulsory psychiatric care, it does not follow that such patients are unable to provide consent for surgical care. Their competence should be assumed and consent should be sought. If it is established with the help of their carers that such patients are also incompetent to provide consent for surgery and that they are at risk of death or serious and permanent disability, then therapy can proceed in their best interests. However, if treatment can be postponed, then this should be done until, as a result of their psychiatric care, patients become able either to consent or to refuse. If this recovery is not predicted, then legal steps may be taken to make elective surgery lawful. As with children, respect should always be shown for as much autonomy as is present.

In adult patients who are permanently incapacitated, and thus unable to provide consent for surgery, the doctrine of necessity obtains, and surgery can proceed in an emergency to save life, to prevent serious and permanent injury. Elective treatment for less grave complaints can also be provided, and in England and Wales is done so under the auspices of the Mental Capacity Act 2005. The associated Code of Practice guides the surgeon in matters of capacity and disclosure; and in dealing with those who have taken steps to influence their treatment, anticipating the time that they will have lost their capacity. These arrangements may manifest either in documentary form, as Advance Decisions; or in person, in the form of persons appointed with a Lasting Power of Attorney.

It is not possible for relatives of incompetent adult patients to sign consent forms for surgery on their behalf. Indeed, to make such requests can be a disservice to relatives, who may feel an unjustified sense of responsibility if the surgery fails. This said, relatives play a vital role in providing background information about the patient, allowing the clinician to assess and then determine what treatment is in the best interests of the patient.

MATTERS OF LIFE AND DEATH

It has been noted that the right of a competent adult to consent to and refuse treatment is unlimited, including the refusal of life-sustaining treatment. Probably the example of this most familiar to surgeons is Jehovah’s Witnesses, who may refuse blood transfusions at the risk of their own lives.

There will be some circumstances in which sustaining the life and health of incompetent patients is judged to be inappropriate. They are no longer able to be consulted; and may not have expressed a view about what their wishes would be in such circumstances. Here, if possible after discussion and consensus with the next of kin, a decision may be made to withhold or to withdraw life-sustaining treatment on behalf of the incompetent

A **Jehovah’s Witness** is a member of a millenarian fundamentalist Christian sect founded in America in 1884. They have their own translation of the Bible which they interpret literally.

patient. The fact that such decisions can be seen as omissions to act does not excuse surgeons from morally and legally having to reconcile them with their ordinary duty of care. Ultimately, this can only be done through arguing that such omissions to sustain life are in the patient's best interests.

The determination of best interests in these circumstances will rely on one of three objective criteria, over and above the subjective perception by the surgeon that the quality of life of the patient is poor. There is no obligation to provide or to continue life-sustaining treatment:

- If doing so is futile, when clinical consensus dictates that it will not achieve the goal of extending life. Thought of in this way, judgements about futility exclude considering the patient's quality of life; and thus can be difficult to justify as long as treatment might stand even a very small chance of success.
- If a patient is imminently and irreversibly close to death – in such circumstances, it would not be in the patient's best interests to prolong life slightly (e.g. through the application of intensive care) when, again, there is no hope of any sustained success. Declining needlessly to interfere with the process of a dignified death can be just as caring as the provision of curative therapy.
- If a patient is so permanently and seriously brain damaged that, lacking awareness of themselves or others, they will never be able to engage in any form of self-directed activity. The argument here is backed up by morally and legally reasoning that further treatment other than effective palliation cannot be in the best interests of the patient as it will provide them with no benefit.

When any of these principles are employed to justify an omission to provide or to continue life-sustaining treatment, the circumstances should be carefully recorded in the patient's medical record, along with a note of another senior clinician's agreement.

Finally, surgeons will sometimes find themselves in charge of the palliative care of patients whose pain is increasingly difficult to control. There may come a point in the management of such pain when effective palliation is possible at the risk of shortening a patient's life because of the respiratory effects of the palliative drugs. In such circumstances, surgeons can with legal justification administer a dose that might be dangerous (although experts in palliative care are sceptical that this is ever necessary with appropriate training). In any case, the argument employed to justify such action refers to its 'double effect': that both the relief of pain and death might follow from such an action. Intentional killing (active euthanasia) is rejected as unlawful malpractice throughout most of the world. A foreseeably lethal analgesic dose is thus regarded as appropriate only when it is solely motivated by palliative intent; and this motivation can be documented.

TRANSPLANTATION

The law and ethics of organ transplantation require more space than this chapter allows. In common with other nations, the United Kingdom has a statutory framework for transplantation, but even among this small group of nations, there is no unanimity of legislation, thus rules for deceased and live donor transplants differ. In general, the rules for defining a dead donor;

for compensating a living donor; and for legitimising a market in organs differ widely. It is strongly recommended that you refer to the rules within your own jurisdiction.

CONFIDENTIALITY

Respect for autonomy does not entail only the right of competent patients to consent to treatment. Their autonomous right extends to control over their confidential information, and surgeons must respect their privacy, not communicate information revealed in the course of treatment to anyone else without consent. Generally speaking, such respect means that surgeons must not discuss clinical matters with relatives, friends, employers and others unless the patient explicitly agrees. To do otherwise is regarded by all the regulatory bodies of medicine and surgery as a grave offence, incurring harsh penalties. For breaches of confidentiality are not only abuses of human dignity, they again undermine the trust between surgeon and patient on which successful surgery and the professional reputations of surgeons depend.

Important as respect for confidentiality is, however, it is not absolute. Surgeons are allowed to communicate private information to other professionals who are part of the healthcare team – provided that the information has a direct bearing on treatment. Here, it is argued that patients have given their implied consent to such communication when they explicitly consent to a treatment plan. Whether implied consent can ever be valid is a matter for public debate, as government attempts to apply the doctrine to tissue donation and access to electronic health records.

Patients cannot expect strict adherence to the principle of confidentiality if it poses a serious threat to the health and safety of others. There will be some circumstances in which confidentiality either must or may be breached in the public interest. For example, it must be breached as a result of court orders or in relation to the requirements of public health legislation. Confidentiality may be waived in the interests of preventing serious crime or to protect the safety of other known individuals who are at risk of serious harm.

RESEARCH

As part of their duty to protect life and health to an acceptable professional standard, surgeons have a subsidiary responsibility to strive to improve operative techniques through research, to assure themselves and their patients that the care proposed is the best that is currently possible. Yet, there is moral tension between the duty to act in the best interests of individual patients and the duty to improve surgical standards through exposing patients to the unknown risks that any form of research inevitably entails.

The willingness to expose patients to such risks may be further increased by the professional and academic pressures on many surgeons to maintain a high research profile in their work. For this reason, surgeons (and physicians, who face the same dilemmas) now accept that their research must be externally regulated to ensure that patients give their informed consent, that any known risks to patients are far outweighed by the potential benefits, and that other forms of protection for the patient are in place (e.g. proper indemnity) in case they are unexpectedly harmed. The administration of such regulation is through

research ethics committees, and surgeons should not participate in research that has not been approved by such bodies. Equally, special provisions will apply to research involving incompetent patients who cannot provide consent to participate and research ethics committees will evaluate specific proposals with great care.

In practice, it is not always clear as to what constitutes 'research' that should be subjected to regulation, as compared with a minor innovation dictated by the contingencies of a particular clinical situation. Surgeons must always ask themselves in such circumstances whether or not the innovation in question falls within the boundaries of standard procedures in which they are trained. If so, what may be a new technique for them will count not as research but as an incremental improvement in personal practice. Nevertheless, major innovations in operative procedure are scrutinised by national regulatory authorities; in the United Kingdom, by the National Institute for Clinical Healthcare Excellence. This process of scrutiny has been designed to ensure that the innovation is safe, efficacious and cost-effective. It is regarded (by the NHS) as a mandatory step when introducing a new interventional procedure.

Equally, surgeons know that exigencies of operative surgery sometimes demand a novel and hitherto undescribed manoeuvre to get the surgeon (and their patient) out of trouble. Providing your solution is necessary, proportionate to the circumstances, performed in good faith and would pass the scrutiny of your peers as reasonable, it is unlikely that any subsequent criticism of your actions could be sustained.

If a proposed innovation passes the criteria for research, it should be approved by a research ethics committee. Such surgical research should also be subject to a clinical trial designed to ensure that findings about outcomes are systematically compared with the best available treatment and that favourable results are not the result of arbitrary factors (e.g. unusual surgical skill among researchers) that cannot be replicated.

MAINTAINING STANDARDS OF EXCELLENCE

To optimise success in protecting life and health to an acceptable standard, surgeons must only offer specialised treatment in which they have been properly trained. To do so will entail sustained further education throughout a surgeon's career in the wake of new surgical procedures. While training, surgery should be practised only under appropriate supervision by someone who has appropriate levels of skill. Such skill can be demonstrated only through appropriate clinical audit, to which all surgeons should regularly submit their results. When these results are unacceptable, no further surgical work of that kind should continue unless further training is undergone under the supervision of someone whose success rates are satisfactory. To do otherwise would be to place the interest of the surgeon above that of their patient, an imbalance that is never morally or professionally appropriate.

Surgeons also have a duty to monitor the performance of their colleagues. To know that a fellow surgeon is exposing patients to unacceptable levels of potential harm and to do nothing about it is to incur some responsibility for such harm when it occurs. Surgical teams and the institutions in which they function should have clear protocols for exposing unacceptable professional performance and helping colleagues to understand

the danger to which they may expose patients. If necessary, offending surgeons must be stopped from practising until they can undergo further appropriate training and counselling. Too often, such danger has had to be reported by individuals whose anxieties have not been properly heeded and who have then been professionally pilloried rather than acknowledged for their contribution to patient safety. Those who participate in closing ranks, and ostracism, share the moral responsibility for any resulting harm to patients.

CONCLUSION

Surgeons have a combination of duties to their patients: to protect life and health, and to respect autonomy; both to an acceptable professional standard. The specific duties of surgeons are shown to follow from these: reasonable practice concerning informed consent, confidentiality, decisions not to provide, or to omit, life-sustaining care, surgical research and the maintenance of good professional standards. The final duty of surgical care is to exercise all these general and specific responsibilities with fairness and justice, and without arbitrary prejudice. Now, at least partly either enshrined in statute or echoed in the English common law, these duties closely reflect the guidance of the General Medical Council.

The conduct of ethical surgery illustrates good citizenship: protecting the vulnerable and respecting human dignity; and equality. To the extent that the practice of individual surgeons is a reflection of such sustained conduct, they deserve the civil respect which they often receive. To the extent that it is not, they should not practise the honourable profession of surgery.

Patient safety

LEARNING OBJECTIVES

To learn:

- The importance of patient safety and the scale of the problem
- Medical errors, their range and definition
- Models for understanding how adverse events and near misses occur
- Patient safety strategies and solutions
- Applying the science of patient safety to practice
- Patient safety principles that are specific to the surgeon
- Dealing with the 'second victim' of a medical error

INTRODUCTION

Medicine will never be a risk-free enterprise. From the beginning of training, doctors are taught that errors are unacceptable and that the philosophy of *primum non nocere* (first, do no harm) should permeate all aspects of treatment. Yet, worldwide, despite all the improvements in treatment and investment in technologies, training and services, there remains the challenge of dealing with unsafe practices, incompetent healthcare professionals, poor governance of healthcare service delivery, errors in diagnosis and treatment and noncompliance with accepted standards.

When errors do occur there continues to be a lack of adequate systems in place to ensure that all those affected are informed and cared for, and that there is a process of analysis and learning to uncover the cause and prevent recurrence of such events. Patient safety has become an established healthcare discipline in its own right thus formalizing approaches to these inadequacies, directing research and offering solutions for the future.

THE PREVALENCE OF ADVERSE HEALTHCARE EVENTS

The aviation and nuclear industries have a much better safety record than healthcare. This became abundantly clear when, in 1999, the Institute of Medicine of the National Academy of Sciences released a report, *To Err is Human: Building a Safer Health System*, that drew widespread attention to the alarming statistics that there were between 44 000 and 98 000 preventable deaths annually due to medical error in American hospitals with some 7000 preventable deaths related to medication errors alone. This experience has been found to be similar in other developed countries and was emphasised by the Bristol Royal Infirmary Inquiry of 2001 into a series of unacceptable paediatric cardiac surgical deaths. The World Health Organization estimates that, even in advanced hospital settings, one in ten

patients receiving healthcare will suffer preventable harm.

The financial burden of unsafe care globally is also compelling resulting as it does in prolonged hospitalization, loss of income, disability and litigation costing many billions of dollars every year.

In the decade or more since the Institute of Medicine report there have been many initiatives to improve patient safety. Some interventions have been shown to reduce errors but many have still not been rigorously evaluated. Overall, it remains unclear whether efforts to reduce errors at national, regional and local levels have yet translated into significant improvements in the safe care of patients. This situation is unlikely to improve significantly while the reporting of adverse events remains low.

COMMON CAUSES OF ADVERSE HEALTHCARE EVENTS

Most medical care entails some level of risk to the patient either from their underlying condition or its treatment which, of itself, may lead to recognised complications or side effects. These episodes are different from **patient safety incidents** which have been described as preventable events or circumstances that could have, or did, result in unnecessary harm to the patient. This might be an adverse event, near miss and no-harm event (Table 12.1).

The most frequent contributing factors that lead to patient safety incidents are listed in Table 12.2. Of these, inadequate communication between healthcare staff, or between medical staff and their patients or family members, ranks highest in frequency.

UNDERSTANDING PATIENT SAFETY INCIDENTS

Understanding the concepts underlying patient safety incidents is useful because it helps to anticipate situations that are likely to

Table 12.1 Patient safety incidents.

Definitions	
An adverse event	An incident which results in harm to the patient
A near miss	An incident that could have resulted in unwanted consequences but did not, either by chance or through a timely intervention preventing the event from reaching the patient
A no-harm event	An incident that occurs and reaches the patient but results in no injury to the patient. Harm is avoided by chance or due to mitigating circumstances

Table 12.2 Factors that contribute to patient safety incidents.

Human factors	Inadequate patient assessment; delays or errors in diagnosis
	Failure to use or interpret appropriate tests
	Error in performance of an operation, treatment or test
	Inadequate monitoring or follow up of treatment
	Deficiencies in training or experience
	Fatigue, overwork, time pressures
	Personal or psychological factors, e.g. depression or drug abuse
System failures	Patient or working environment variation
	Lack of recognition of the dangers of medical errors
	Poor communication between healthcare providers
	Inadequate staffing levels
	Disconnected reporting systems or over-reliance on automated systems
	Lack of coordination at handovers
	Drug similarities
Medical complexity	Environment design, infrastructure
	Equipment failure, due to lack of parts or skilled operators
	Cost-cutting measures by hospitals
	Inadequate systems to report and review patient safety incidents
	Advanced and new technologies
	Potent drugs, their side effects and interactions
	Working environments – intensive care, operating theatres

lead to errors and highlights the areas where preventative action can be taken.

The problem of error can be viewed in two ways – from a person approach or from a system approach.

The person approach

Human performance principles tell us that humans are fallible and that errors can occur through doing the wrong thing – errors of commission; failure to act – errors of omission; or errors of execution – doing the right thing incorrectly. These principles also tell us that, by understanding the reasons why adverse events and near misses occur and by applying the lessons learnt from past events, future errors can be prevented. However, for most errors the person approach on its own tends to blame the individual and restricts learning.

The system approach

Health systems add complex organisational structures to human fallibility thus substantially increasing the potential for errors. A systems approach to error recognises that adverse events rarely have a single isolated cause and that they are best addressed by examining why the system failed rather than who made the mistake. James Reason, former Professor of Psychology at Manchester University, has stated that, 'We cannot change the human condition but we can change the conditions under which people work so as to make error less provoking'.

Heinrich's safety pyramid

Developed in 1931, Heinrich's safety pyramid theorised that unsafe acts or near misses lead to minor injuries and over time to a major injury. The accident pyramid proposes that for every 300 near misses there are 29 minor injuries and one major injury (Figure 12.1). **Risk assessment**, which is a step in risk management that calculates the value of risk related to a situation or hazard, has shown us that, what prevents patients from being hurt, is not only by reducing the number of mistakes but rather by increasing the number of defences set up against the consequences of mistakes. The key message is that near misses provide the best data about the reliability of safety systems. It is, therefore, most important to report near misses as well as adverse events to ensure that defences against adverse events are built and sustained.

Swiss cheese model

Reason's theory of accident causation, often referred to as the Swiss cheese model, is as well known in the aviation and nuclear power industries as it is in healthcare. His model takes Heinrich's concept forward and proposes the notion of **active failures** – acts that are committed by those at the coal face such as slip-ups, lapses or mistakes, and **latent conditions** – created by decisions taken at a higher level within the organisation leading, for example, to staff shortages or time pressures.

Figure 12.1 Heinrich's pyramid.

Figure 12.2 Reason's Swiss cheese model.

Figure 12.3 SHELL model.

Reason hypothesised that all organisations operating in potentially harmful environments tend to build up defences against potential damage and that these defences can be broken down by active failures or latent conditions. Although latent conditions are not harmful in themselves, they lie dormant within the system before combining with active failures to bypass the defences.

The defences in this model are represented as slices of Swiss cheese. This is because, instead of being intact, they are, in reality, full of holes or defects which represent either active failures or latent conditions. What is more, these gaps in the defences may not be static but can open and close and change position over time. Danger arises when a set of holes line up for a brief window allowing a potential hazard to become a fully blown accident. Each slice of cheese or defence is an opportunity to prevent an accident and the more slices there are and the fewer holes the less likely it is that an accident will occur or harm be done to a patient (Figure 12.2).

While healthcare workers are often at the sharp end of an error they are also often error catchers. It is the clinician's responsibility to observe, discuss and highlight latent conditions before adverse events occur and ensure the appropriate defences are in place.

SHELL model

Human factors is the study of the interrelationship between humans, the tools they work with and the environment in which they work. Working with this concept the SHELL model, developed in aviation, is designed to help understand the conditions that lead to adverse events.

The SHELL concept is named after the initial letters of its components – **Software, Hardware, Environment and Liveware** (Figure 12.3). In the centre of the model is the human operator, or the Liveware, represented by 'L'. This may be any individual whose job is relevant to patient care. It is the most flexible component in the system but may be unpredictable due to individual factors, such as personality, motivation, stress tolerance, skills, knowledge and attitudes. To overcome these intrinsic limitations the interface with the other components of the SHELL model must be adapted and matched to the Liveware component for optimum performance.

The first interface, the Liveware–Hardware has much to do

with the ergonomic design of medical devices such that they should make it difficult for an operator to make a mistake.

The Liveware–Software interface encompasses the non-physical aspects of the system, such as manuals, checklists and computer programs. An adequate Liveware–Software interface should produce a situation where procedural omissions are difficult to make.

The Liveware–Environment interface may include stressors in the physical environment that have to be coped with, such as noise, poor acoustics and overcrowding.

The Liveware–Liveware interface is the interface of interpersonal communication. It embraces concepts, such as team coordination, conflict resolution and the continuity of information flow in the care of patients.

In the SHELL model diagram the edges of the blocks are uneven. This is to illustrate that the interdependent components are constantly changing and will never match perfectly. Human factors are concerned with minimising the mismatch between the different components (Summary box 12.1).

Summary box 12.1

Understanding patient safety incidents

- Errors can be viewed from a person-centred or system approach
- The majority of near misses or adverse events are due to system factors
- Understanding why these errors occur and applying the lessons learnt will prevent future injuries to patients
- It is important to report all near misses or adverse events so that we can constantly learn from mistakes
- Error models can help us understand the factors that cause near misses and adverse events and also direct us to where our defences against harm need to be improved

STRATEGIES FOR PATIENT SAFETY

International

Safety is everybody's business. Since the Institute of Medicine report, the World Health Organization has adopted a strong

leadership role with many initiatives aimed at addressing safety challenges, notably 'Clean care is safer care', to ensure sustainable hand hygiene; and, 'Safe surgery saves lives', a programme that includes the Surgical Safety Checklist aimed at decreasing the incidence of operative complications. It has also identified priority areas for patient safety research and has introduced 'patient safety alerts', an information-sharing resource to learn from patient safety incidents.

Developed countries

Many governments and national organisations in developed countries have developed important strategies aimed at delivering safety and quality in healthcare. These include:

- regulating and licensing of physicians and healthcare institutions;
- developing and adopting policies for patient safety and quality improvement;
- providing patient safety education programmes;
- instituting national clinical audits;
- reporting (and learning from) adverse events;
- setting up agencies to resolve concerns about the practice of doctors by providing case and incident management services.

Developing countries

Developing countries share many aspirations and similar challenges with developed countries. However, they also face issues that are different and require different strategies. The probability of a patient being harmed in hospital is higher with, for example, the risk of healthcare-associated infection being as much as 20 times higher than in developed countries. At least 50 per cent of medical equipment in developing countries is unusable or only partly usable and often the equipment is not used due to lack of parts or necessary skills. In some countries, the proportion of injections given with syringes or needles reused without sterilisation is as high as 70 per cent. Each year, unsafe injections cause 1.3 million deaths, primarily due to transmission of hepatitis B virus, hepatitis C virus and HIV. Clearly, these issues need to be met with a specific range of initiatives.

Institutional or hospital

Team working and training

In order to decrease errors and increase patient safety many medical team training programmes have now been developed internationally, often based on **crew resource management (CRM)** programmes, the team training strategy used in the aviation industry. This kind of training heightens safety awareness, improves communication and decision-making behaviours and has been shown to both reduce errors and surgical mortality. Some of these programmes are domain-specific (such as in anaesthesia); others are multidisciplinary (emergency department or operating room based); some rely on state of the art simulators (critical care); others rely primarily on classroom instruction.

Motivated and well-prepared healthcare workers who are educated and trained to work together can reduce risks to patients, themselves and their colleagues, especially if they manage incidents positively and make the most of opportunities to learn from adverse events and near misses. Increasingly, healthcare institutions will have to provide this kind of educational support for their workforce.

Using information technology

A major barrier to providing quality care to patients is the way health information is collected and stored in paper-based records often in locations remote from where care is provided. Paper-based record systems are more susceptible to errors and permit fewer checks than electronic systems. There is now good evidence that the routine use of information and communication technology (ICT) will contribute greatly to the use of real-time data to support clinical decisions, thereby supporting healthcare workers and patients to more easily access reliable health information and reduce medical errors. Good examples include computerised patient records and physician order entry systems for medication prescribing.

Redesigning systems and processes

Improvements in healthcare are likely only if the systems and processes are designed to eliminate small contributory errors across a wide range of care processes. Attempts at radical system redesign in order to improve quality and safety across an organisation, which are relatively common in industry, have so far been infrequent in healthcare. Perhaps the most successful example of system redesign in industrial settings has been the Toyota Production System, or '**Lean**' methodology which, in essence, involves the elimination of waste through continuous improvement with waste including anything that does not give customer value.

In healthcare, the customer is the patient and reducing waste includes eliminating error. In medical settings, there is good evidence of the benefits of '**Lean**' in improving efficiency, reducing costs and improving patient satisfaction as well as potentially reducing error (Summary box 12.2).

Summary box 12.2

Strategies for patient safety

- The WHO has established a number of international initiatives for patient safety
- Various national approaches are being undertaken by countries in the developed world
- In developing countries patient safety issues are more acute due to a lack of resource, and face different challenges
- Hospitals or institutions that will offer the greatest patient safety systems in the future will include those that foster team working, maximise the use of information technology and are prepared to realign their systems and processes

PATIENT SAFETY AT THE COALFACE

Communicating openly with patients and their carers and obtaining consent

A patient-centred approach by medical staff, with involvement of patients and their carers as partners is now recognised as being of fundamental importance. There are better treatment outcomes and fewer errors when there is good communication while poor communication is a common reason for patients taking legal actions.

Involving patients in and respecting their right to make decisions about their care and treatment is crucial. Explaining risk is

Table 12.3 Information to be provided when seeking consent for surgery.

Details and uncertainties of the diagnosis
The purpose and details of the proposed surgery
Known possible side effects and potential complications
The likely prognosis
Other options for treatment, including the option not to treat
Explanation of the likely benefits and probabilities of success for each option
The name of the doctor who will have overall responsibility
A reminder that the patient can change his or her mind at any time

a difficult but important part of good communication. It requires skill to explain the potential for harm of a procedure so that it is fully understood because patients vary in their perception and understanding; and it is often difficult to assess the trade-offs between harm and benefit.

Obtaining consent for surgery requires that surgeons provide information to help patients to understand the positives and negatives of their various treatment options (Table 12.3). If only for the purposes of defending claims, hospitals invariably make signed consent mandatory. However, patients should be allowed to make these informed decisions without coercion or manipulation. Consent should be obtained by someone who is capable of performing the surgery and this should be taken when the patient is fully aware, especially in the non-urgent situation, well before the surgical procedure (see also Chapter 11).

Communicating honestly with patients after an adverse event, or **open disclosure**, includes a full explanation of what happened, the potential consequences, and what will be done to fix the problem. Safe care also involves taking care of the patient after the event, ensuring that the problem does not happen again, and a sincere offer of regret or apology, as appropriate.

Professional behaviour and maintaining fitness to practice

Professionalism is an important component of patient safety. This embraces those attitudes and behaviours that serve the patient's best interests above and beyond other considerations. Organisations responsible for maintaining ethical standards include professionalism as one of those standards by which healthcare workers are judged.

Fitness to work or practice – **competence** – refers not just to knowledge and skills but also to the attitudes required to be able to carry out one's duties. Monitoring their fitness for work is the responsibility of each individual and also their employers and professional organisations. Healthcare workers are now required to have transparent systems in place to identify, monitor and assist them to maintain their competence. **Credentialing** is one way that is used to ensure that clinicians are adequately prepared to safely treat patients with particular problems or to undertake defined procedures.

Reporting adverse events and near misses

Adverse events and near misses go unreported for many reasons including a fear of blame and the potential for litigation. **Clinical**

risk management is a specific task, based upon risk identification, analysis and control of events, carried out within a 'blame-free' environment. Data collected from these episodes should be collated and learnt from at an institutional level and by uploading to a national database. Doctors should be familiar with the systems that operate within their own working environment.

Complaints from a patient or carer often highlight a problem that, when analysed, provides opportunities for reducing adverse events and near misses. Poor communication is often the cause and knowing how to manage complaints is an important part of providing better healthcare. There is wide acceptance for the need for complaints to be made easily and effectively, such that now, more and more **patient advocacy** units provide a range of options for resolving complaints including the provision of information, mediation, and the setting up of conciliation meetings between the parties.

Staff communication, understanding the work environment and working well within it

Nowhere is team working more important than in managing the flow of information within healthcare. Poor communication can lead to misinformation to patients and staff, delays in diagnosis, treatment and discharge as well as in failures to follow up on test results. On the other hand, good team work, good communication and continuity of care reduce errors and improve patient care.

Stress, tiredness and mental fatigue in the workplace are significant occupational health and safety risks in healthcare. There is good evidence linking tiredness with medical errors. Fatigue can also affect well-being by causing depression, anxiety and confusion, all of which negatively impact on clinician performance. Organisations and individuals each bear the responsibility for managing working environments and practices so as to reduce fatigue and stress.

Prescribing safely

Prescribing medication is common to almost all strands of medical practice and patients are vulnerable to mistakes being made in any one of the many steps involved in the ordering, dispensing and administration of medications (Summary box 12.3). Accuracy requires that all steps are correctly executed. Unfortunately, medication errors are common and their many causes include:

- poor assessment or inadequate knowledge of patients and their clinical conditions;
- inadequate knowledge of the medications;
- dosage calculation errors;
- illegible hand writing;
- confusion regarding the name or the mixing up of medications.

PATIENT SAFETY AND THE SURGEON

Surgery is one of the most complex health interventions to deliver. More than 100 million people worldwide require surgical treatment every year for different reasons. Problems associated with surgical safety in developed countries account for half of the avoidable adverse events that result in death or disability.

The 'more than one cause' theory of accident causation can be aptly applied to many aspects of surgical patient care during

Summary box 12.3**Patient safety at the coalface requires**

- Communicating well with patients and their carers
- Professionalism, as another essential component of patient safety
- Clinical risk management and patient advocacy and their roles in adverse events and patient complaints
- Team working and information flow as well as managing the work environment
- Recognising the pitfalls to safe prescribing

the perioperative period. Cuschieri and others have described surgical **coalface errors** as those that can potentially be committed by surgeons during the care of their patients and include:

- diagnostic and management errors;
- resuscitation errors;
- prophylaxis errors;
- prescription/parenteral administration errors;
- situation awareness, identification and teamwork errors;
- technical and operative errors.

Situation awareness – identifying teamwork errors

Operating rooms have been described as ‘among the most complex political, social, and cultural structures that exist, full of ritual, drama, hierarchy, and too often conflict’. In such an environment, systems should seek to prevent error by improving workplace preparedness and by incorporating defences so as to reduce human error or minimise its consequence. Well recognised and potential errors include:

- the wrong patient in the operating room;
- surgery performed on the wrong side or site;
- the wrong procedure performed;
- failure to communicate changes in the patient’s condition;
- disagreements about proceeding;
- retained instruments or swabs (Figure 12.4).

All these events are catastrophic for the patient and almost invariably occur through a lack of communication. This means that all theatre staff should follow protocols and be familiar with the underlying principles supporting a uniform approach to caring for patients.

Checklists

Checklists in the operating theatre environment are now accepted as standard safety protocols since the ‘Safe Surgery Saves Lives’ Study Group at the World Health Organization published their results. The use of a perioperative surgical safety checklist in eight hospitals around the world was associated with a reduction in major complications from 11.0 per cent before, to 7.0 per cent after, the introduction of the checklist.

The surgical safety checklist identifies specific checks to be carried out at three obligatory time points (Figure 12.5). The items are not intended to be comprehensive and additions and modifications are encouraged.

We now know that the benefits of standardisation of surgical processes need not be limited to the operating room; several studies have shown that the majority of surgical errors (53–70

Figure 12.4 Axial and coronal magnetic resonance images demonstrating a well-defined abdominal mass with whorled stripes in fluid-filled central cavity. (Arrows) This 60-year-old woman had had an abdominal hysterectomy ten years previously and presented with a pyrexia and flank pain. The cause was due to the late presentation of a retained surgical swab.

per cent) occur outside the operating room, before or after surgery, and that a more substantial improvement in safety can be achieved by targeting the entire surgical pathway.

There is no question that checklists are tools that improve outcomes. However, there are some important considerations. Checklists are suited to solving specific kinds of problems, but not others. Even in comparison to aviation, managing patients involves an enormous amount of coordinated, time-pressured decision-making, and potential delays. Checklists are simple reminders of what to do, and unless they are coupled with

attitude change and efforts to remove barriers to actually using them, they will have limited impact. Finally, if one begins to believe that safety is simple and that all it requires is a checklist, there is a danger of abandoning other important efforts to achieve safer, higher quality care.

Technical and operative errors

In surgery, the person rather than systems approach emphasizes the accountability of the surgeon who, unlike colleagues in other medical disciplines, when operating, is the treatment.

During a surgical procedure, for example, there may be a specific action that, of itself, may be the error, such as the inadvertent cutting of the common bile duct during a cholecystectomy (Figure 12.6). The practical value of this kind of interpretation is that, provided latent conditions are excluded, it gives a sense of responsibility to surgeons and it may also help to point to the most effective pathway for remediation, by counselling or retraining, as against reassessing the system and putting in place further safeguards.

Central to operative performance is proficiency which is an acquired state, honed by sound teaching, practice and repetition, by which a surgeon consistently performs operations with good outcomes. In cognitive psychology, high surgical proficiency is a state of automatic unconscious processing, with the execution being effortless, intuitive and untiring; as opposed to non-proficient execution which is characterized by conscious control processing requiring constant attention and resulting in slow, deliberate execution and inducing fatigue. The transition from one state to the other is better known as the 'learning curve'. This should not carry negative connotations for trainee surgeons who might be at the conscious processing stage but still perform a perfectly good operation although it might take longer and be more tiring.

Failures in operative technique include:

- cognitive errors of judgement, such as failure or late conversion of a difficult laparoscopic procedure into an open one;
- procedural, when the steps of an operation are not followed, or omitted;
- executional, when, for example, too much force is used which may result in damage that may or may not have consequences;
- misinterpretation, which is unique to minimal access surgery and is a function of the misreading of a two-dimensional image;
- misuse of instrumentation, such as with energised dissection modalities, for example, diathermy;
- missed iatrogenic injury either at the time of surgery or diagnosed late.

CARING FOR THE SECOND VICTIM

The first victim of an adverse event is the patient and their family. Doctors do not purposely set out to injure patients but when it does happen due to an error they may experience a range of emotions including distress, shame, guilt, fear and depression. To that extent they can be regarded as a 'second victim'. Indeed, the wound to the second victim may at times be profound, leading to physical and psychological disturbances. These problems can last many months or years, especially in cases of severe disablement or death. Under such circumstances it is easy to see how a doctor's distress can lead to further deficits in patient care.

Coping with the impact of error can be challenging and the 'second' victim requires management. Doctors often find it difficult to admit to and cope with mistakes or resort to employee support systems. Dysfunctional coping strategies include denial, blaming others or refusal to discuss the issue.

Figure 12.6 Radiograph showing an iatrogenic bile duct injury.

There are two recognised and helpful management strategies. The first is the problem-focused strategy which includes attempting to deal with the problem itself and this might include accepting responsibility for the mistake or disclosing the error and apologising to the patient. The second is the emotion-focused strategy which takes in attempts to deal with the negative emotions aroused by the problem. Here it is important that the second victim opens up lines of communication and it is equally important that professional colleagues show compassion and empathy by sensing difficulty or poor coping, providing a sounding board and by offering advice and support (Summary box 12.4).

Summary box 12.4

Patient safety and the surgeon and caring for the second victim

- Errors that can be made by surgeons in their overall management of patients
- Errors that occur in the operating theatre and how they can be mitigated
- The role of checklists in patient safety
- Performance proficiency and understanding technical and operative failures
- The 'second victim' in medical error and how this situation can be best managed

Diagnostic imaging

LEARNING OBJECTIVES

To understand:

- The advantages of good working relationships and close collaboration with the imaging department in planning appropriate investigations
- The basic principles of radiation protection and know the law in relation to the use of ionising radiation
- The principles of different imaging techniques and their advantages and disadvantages in different clinical scenarios

INTRODUCTION

Appropriate surgical management of the patient relies on correct diagnosis. While clinical symptoms and signs may provide a firm diagnosis in some cases, other conditions will require the use of supplementary investigations including imaging techniques. The number and scope of imaging techniques available to the surgeon have dramatically increased within a generation from a time when radiographs alone were the mainstay of investigation. The development of ultrasound and colour Doppler, computed tomography (CT) and magnetic resonance imaging (MRI) has enabled the surgeon to make increasingly confident diagnoses and has reduced the need for diagnostic surgical techniques such as explorative laparotomy. Faced with such a plethora of imaging to choose from, it is important that the patient is not sent on a journey through multiple unnecessary examinations.

As a basic principle, the simplest, cheapest test should be chosen that it is hoped will answer the clinical question. This necessitates knowledge of the potential complications and diagnostic limitations of the various methods. For example, in a patient presenting with the clinical features of biliary colic, an ultrasound examination alone may give enough information to enable appropriate surgical management. In more complex cases, it may be more efficient to opt for a single, more expensive investigation, such as CT, rather than embarking on multiple simpler and cheaper investigations that may not yield the answer. The choice of technique is often dictated by equipment availability, expertise and cost, as well as the clinical presentation. However, it must be emphasised that, not infrequently, the most valuable investigation is a prior radiograph; this not only reduces the cost and the amount of radiation a patient receives but very often improves patient care.

HOW TO REQUEST IMAGING

Best practice depends on close collaboration between the radiologist and the referrer and must take into account local expertise and access to facilities. When requesting imaging, consider what it is that you want to know from the investigation. Give a provisional diagnosis or state the clinical problem. If there is uncertainty over the best method to answer the clinical problem, then discussion with a radiologist is always worthwhile, informally or within the context of a clinicoradiological meeting or a multidisciplinary team (MDT) meeting.

As well as the basic demographic information stored on the radiology information system (RIS), it is important to provide relevant past medical history, e.g. diabetes, epilepsy, renal failure, allergies and anticoagulation, all of which can affect which contrast agent can be given safely, and the date of the last menses in women of childbearing potential.

INTERPRETING IMAGES

Complex imaging may best be left to radiologists to interpret, but the clinician should be able to examine radiographs to exclude major abnormalities. The plain radiograph can be systematically examined using the system in Summary box 13.1.

The systematic approach to examining a radiograph varies according to the part of the body being imaged. For instance, for a radiograph of an extremity, the alignment, the cortices and the medullary cavity of the individual bones, the joints and the soft tissues all need to be assessed on each view. You should develop, learn and practise your own method for ensuring that you study all of these in each case. This will take a long time when you start, but speed comes with practice.

Summary box 13.1**A simple system for checking radiographs**

Label	Name of patient
Site	Date of examination
	Side (check marker)
	What part is the film centred on?
	Does the film cover the whole area required?
	Is there more than one view?
Quality	Is the penetration appropriate?
Compare	How have the appearances changed from previous images?
Conclude	Is the diagnosis clear?
	Is further imaging needed?

HAZARDS OF IMAGING**Contrast media**

There has been a dramatic increase in the use of contrast agents in recent years, mainly related to the increasing use of CT. Potential problems include allergic reaction and nephrotoxicity. The newer low-osmolality contrast media (LOCM) are 5–10 times safer than the older higher-osmolality agents. Reactions are rare: serious reactions occur in about 1:2500 cases and life-threatening reactions in about 1:25 000 cases. The risk of sudden death, however, has not changed with the new agents. Local policies for dealing with patients at increased risk vary between departments and, indeed, between countries. A recent publication from the Royal College of Radiologists (RCR) in the UK does not recommend routine steroid prophylaxis for patients at increased risk of allergic reaction, but rather the use of a LOCM and observation of the patient for 30 minutes after injection with the intravenous cannula still *in situ*, as most serious reactions occur shortly after injection. Guidelines from the European Society of Uradiology (ESUR), however, continue to advocate the use of steroids.

In patients with diabetes or renal impairment, a recent creatinine level should be available. The radiologist should be informed of any history of renal impairment, as all contrast media are nephrotoxic in patients with impaired renal function. The risks and benefits of contrast administration need to be carefully assessed in these patients and, if contrast is given, the patient should be well hydrated and the lowest dose of a LOCM should be given. The British RCR does not recommend the routine use of *N*-acetylcysteine for renal protection.

Concerns about lactic acidosis in patients on metformin receiving contrast led to various recommendations for stopping the metformin. The latest RCR recommendations are that it can be continued in patients receiving 100 mL or less of intravenous contrast (which is the case for the majority of CT examinations) who are thought to have normal renal function. Other patients, including those who have intra-arterial contrast for angiography, should be discussed with the radiologist.

Gadolinium-containing contrast agents are used in MRI examinations. Allergic reactions to these agents are rare; mild reactions may occur in around 1:200 patients, with severe reac-

tions in around 1:10 000 patients. However, they can be nephrotoxic in patients with pre-existing renal failure. In addition, they are associated with a risk of nephrogenic systemic fibrosis (NSF), a serious life-threatening condition whereby connective tissue forms in the skin causing it to become coarse and hard. NSF may also affect other organs, including joints, muscle, liver and heart. High risk gadolinium-containing contrast agents are contraindicated in severe renal failure, in neonates and in the perioperative period of liver transplantation, and are not recommended in pregnancy.

HAZARDS OF IONISING RADIATION

The majority of ionising radiation comes from natural sources on the earth and cosmic rays, and this makes up the background radiation. However, medical exposure accounts for around 15 per cent of the total received by humans. The effects of ionising radiation can be broadly divided into two groups. The first group comprises predictable, dose-dependent tissue effects and includes, for example, the development of cataracts in the lens of the eye. These effects are important for those chronically exposed to radiation, including those using image intensifiers regularly. The second group comprises the all or nothing effects such as the development of cancer (termed stochastic). These effects are not dose dependent, but increase in likelihood with increased radiation dose.

The risk of radiation-induced cancer for plain films of the chest or extremities is very small, of the order of 1:1 000 000. However, that risk rises considerably for high-dose examinations such as CT of the abdomen or pelvis, where the estimated lifetime excess risk of cancer increases to the order of 1:1000. Use of CT has increased dramatically in the last 20 years, with a 12-fold increase in the UK, and it has been estimated that up to 30 per cent of these examinations may be unnecessary. Obviously, the risk of such examinations has to be balanced against the benefit to the patient in terms of increased diagnostic yield, and must also be viewed in the context that the lifetime risk of cancer for people generally is about 1:3. Nevertheless, the increased risk is important since it is iatrogenic and applied to a large population. Therefore, techniques that do not use ionising radiation, such as ultrasound and MRI, should be carefully considered as alternatives, particularly in children and young people.

CURRENT LEGISLATION

In the UK, the Ionising Radiation (Medical Exposure) Regulations (IRMER) introduced in 2000 impose on the radiologist the duty to the patient to make sure that all studies involving radiation (plain radiographs, CT and nuclear medicine) are performed appropriately and to the highest standards. Inappropriate use of radiation is a criminal offence, so investigations involving radiation need careful consideration in order to prevent wasteful use of radiology (Summary box 13.2).

Summary box 13.3 gives a summary of the responsibilities of both the radiologist and the referrer.

The RCR has published a book, *Making the Best Use of a Department of Clinical Radiology* (6th edition, 2012), which has been adopted in many European countries. Local rules and guidelines are in place to deal with particular circumstances. Table 13.1, showing the radiation doses for common procedures, is taken from this publication.

Summary box 13.2**Wasteful use of radiology**

Results unlikely to affect patient management

Positive finding unlikely

Anticipated finding probably irrelevant for management

Do I need it?

Investigating too often

Before disease could be expected to have progressed or resolved

Do I need it now?

Repeating investigations done previously

Other hospital (?)

GP (?)

Has it been done already?

Failing to provide adequate information

Therefore wrong test performed or essential view omitted

Have I explained the problem?

Requesting wrong investigation

Discuss with radiologist

Is this the best test?

Over-investigating

Are too many investigations being performed?

After: *Making the Best Use of a Department of Clinical Radiology*, 6th edn. Royal College of Radiologists, 2007.

Summary box 13.3**Responsibilities**

- Radiologists have a legal responsibility to keep imaging as safe as possible
- The referrer has a duty to balance risk against benefit
- The referrer must provide adequate clinical details to allow justification of the examination
- Avoid using portable (mobile) x-ray machines whenever practical
- Take all precautions when using an image intensifier
- The gonads, eyes and thyroid are especially vulnerable to radiation and should be protected

There are special considerations for portable and fluoroscopy units. The longer an operator keeps the fluoroscopy unit running, the higher the dose of radiation to all in the vicinity. Portable x-ray machines and fluoroscopic imaging equipment use much more radiation to achieve the same result. The staff, and patients in the next bed, are at risk when portable equipment is used. The result is also of lower quality, so portable x-ray machines should not be used unless absolutely necessary.

When using the image intensifier, lead aprons, thyroid shields, lead glasses and radiation badges should always be worn. Pregnancy in the female patient or staff must be excluded.

DIAGNOSTIC IMAGING**Basic principles of imaging methods****Conventional radiography**

Despite the fact that it is over a hundred years since the discovery of x-rays by Roentgen in 1895, conventional radiography continues to play a central role in the diagnostic pathway of many acute surgical problems and particularly in chest disease, trauma and orthopaedics.

X-rays emitted from an x-ray source are absorbed to varying degrees by different materials and tissues and therefore cause different degrees of blackening of radiographic film, resulting in a radiographic image. This differential absorption is dependent partly on the density and the atomic number of different substances. In general, higher-density tissues result in a greater reduction in the number of x-ray photons and reduce the amount of blackening caused by those photons. In terms of conventional radiographs, a large difference in tissue structure and density is required before an appreciable difference is manifested radiographically. The different densities visible consist of air, fat, soft tissue, bone and mineralisation, and metal. Different soft tissues cannot be reliably distinguished as, in broad terms, they possess similar quantities of water (Figure 13.1). Manipulation of x-ray systems and x-ray energies, as used in circumstances such as mammography, may allow better differentiation between some soft-tissue structures.

Despite this inherent lack of soft-tissue contrast, conventional radiography has many advantages. It is cheap, universally available, easily reproducible and comparable with prior examinations and, in many instances, has a relatively low dose of ionising radiation in contrast to more complex examinations. However, injudicious repeat radiography, particularly of the abdomen, pelvis and spine, can easily result in doses similar to CT.

The lack of soft-tissue contrast allows little assessment of the internal architecture of many abdominal organs. To obviate

Figure 13.1 Supine abdominal radiograph of a patient with small bowel obstruction demonstrating multiple dilated small bowel loops. The different densities visible are air (within the bowel), bones, soft tissues and fat. The different soft tissues, subcutaneous and intra-abdominal, cannot be differentiated.

Table 13.1 Typical effective doses from diagnostic medical exposure in the 2000s.

Diagnostic procedure	Typical effective dose (mSv)	Equivalent no. of chest radiographs	Approximately equivalent period of natural background radiation ^a
Radiographic examinations			
Limbs and joints (except hip)	<0.01	<0.5	<1.5 days
Chest (single posteroanterior film)	0.02	1	3 days
Skull	0.07	3.5	11 days
Thoracic spine	0.7	35	4 months
Lumbar spine	1.3	65	7 months
Hip	0.3	15	7 weeks
Pelvis	0.7	35	4 months
Abdomen	1.0	50	6 months
Intravenous urography (IVU)	2.5	125	14 months
Barium swallow	1.5	75	8 months
Barium meal	3	150	16 months
Barium follow-through	3	150	16 months
Barium enema	7	350	3.2 years
CT head	2.3	115	1 year
CT chest	8	400	3.6 years
CT abdomen or pelvis	10	500	4.5 years
Radionuclide studies			
Lung ventilation (¹³³ Xe)	0.3	15	7 weeks
Lung perfusion (^{99m} Tc)	1	50	6 months
Kidney (^{99m} Tc)	1	50	6 months
Thyroid (^{99m} Tc)	1	50	6 months
Bone (^{99m} Tc)	4	200	1.8 years
Dynamic cardiac (^{99m} Tc)	6	300	2.7 years
PET head (18F-FDG)	5	250	2.3 years

^aUK average background radiation = 2.2 mSv per year; regional averages range from 1.5 to 7.5 mSv.

18F-FDG, 18F-2-fluoro-2-deoxy-D-glucose; CT, computed tomography; ^{99m}Tc, ^{99m}technetium; PET, positron emission tomography.

this problem, techniques employing the administration of contrast material combined with radiography have long been used. These techniques include intravenous urography and barium examinations (Figure 13.2). In intravenous urography (IVU), intravenous administration of iodinated contrast material initially results in opacification of the renal parenchyma, followed by opacification of the pelvicalyceal system, ureters and bladder, allowing identification of pelvicalyceal morphology and filling defects (Figure 13.3). Iodinated contrast material may even be instilled retrogradely into the bladder per urethra and combined with radiographs obtained during micturition to allow the assessment of the lower urinary tract.

A further modification of conventional x-rays uses fluorescent screens to allow real-time monitoring of organs and structures as opposed to the 'snapshot' images obtained with radiographs. This is used to follow the passage of barium through the bowel, obtaining dedicated images at specific points of interest only. Motility of the bowel can also be assessed in this way. Fluoroscopy is used extensively in interventional radiology and, in particular, in vascular intervention by allowing real-time assessment of the passage of intravascular iodinated contrast and the acquisition of multiple images per second to diagnose

intravascular lesions and to guide treatment. Naturally, with the more sustained use of ionising radiation, the cumulative doses tend to be greater than obtaining a conventional radiograph.

Ultrasound

Ultrasound is the second most common method of imaging. It relies on high-frequency sound waves generated by a transducer containing piezoelectric material. The generated sound waves are reflected by tissue interfaces and, by ascertaining the time taken for a pulse to return and the direction of a pulse, it is possible to form an image. Medical ultrasound uses frequencies in the range 3–20 MHz. The higher the frequency of the ultrasound wave, the greater the resolution of the image, but the less depth of view from the skin. Consequently, abdominal imaging uses transducers with a frequency of 3–7 MHz, while higher-frequency transducers are used for superficial structures, such as musculoskeletal and breast ultrasound. Dedicated transducers have also been developed for endocavitary ultrasound such as transvaginal scanning and transrectal ultrasound of the prostate, allowing high-frequency scanning of organs by reducing the distance between the probe and the organ of interest (Figure 13.4). A further application of dedicated probes has been in the field of

Figure 13.2 Barium examination of the small bowel demonstrates a focal short segment stricture of the distal ileum in a patient with Crohn's disease.

Figure 13.3 Intravenous urogram in a patient with macroscopic haematuria. There are focal irregular filling defects in the left side of the bladder and the right renal pelvis, consistent with multifocal transitional cell carcinomas.

endoscopic ultrasound, allowing exquisite imaging of the wall of a hollow viscus and the adjacent organs such as the gastric wall and the pancreas.

Reflection of an ultrasound wave from moving objects such as red blood cells causes a change in the frequency of the ultrasound wave. By measuring this frequency change, it is possible to calculate the speed and direction of the movement. This principle forms the basis of Doppler ultrasound, whereby velocities within major vessels as well as smaller vessels in organs such as the liver and the kidneys can be measured. Doppler imaging is widely used in the assessment of arterial and venous disease, in which stenotic lesions cause an alteration in the normal velocity. Furthermore, diffuse parenchymal diseases, such as cirrhosis, may cause an alteration in the normal Doppler signal of the affected organ.

The advantages of ultrasound are that it is cheap and easily available. It is the first-line investigation of choice for assessment of the liver, the biliary tree and the renal tract (Figures 13.5 and 13.6). Ultrasound is also the imaging method of choice in obstetric assessment and gynaecological disease. High-frequency trans-

Figure 13.4 Longitudinal transvaginal ultrasound scan of the uterus demonstrating thickening of the endometrium in a patient during the secretory phase of the menstrual cycle.

Figure 13.5 Transverse ultrasound image of the liver in a patient with colorectal cancer shows a solitary liver metastasis.

ducers have made ultrasound the best imaging technique for the evaluation of thyroid and testicular disorders in terms of both diffuse disease and focal mass lesions. It is also an invaluable tool for guiding needle placement in interventional procedures such as biopsies and drainages, allowing direct real-time visualisation of the needle during the procedure.

Ligament, tendon and muscle injuries are also probably best imaged in the first instance by ultrasound (Figure 13.7). The ability to stress ligaments and to allow tendons to move during the investigation gives an extra dimension, which greatly improves its diagnostic value. The use of 'panoramic' or 'extended field of view' ultrasound (Figure 13.8) provides images that are more easily interpreted by an observer not performing the examination, and are of particular assistance to surgeons planning a procedure. Ultrasound will demonstrate most foreign bodies in soft tissues, including those that are not radio-opaque.

The disadvantages of ultrasound are that it is highly operator dependent, and most of the information is gained during the actual process of scanning as opposed to reviewing the static images. Another drawback is that the ultrasound wave is

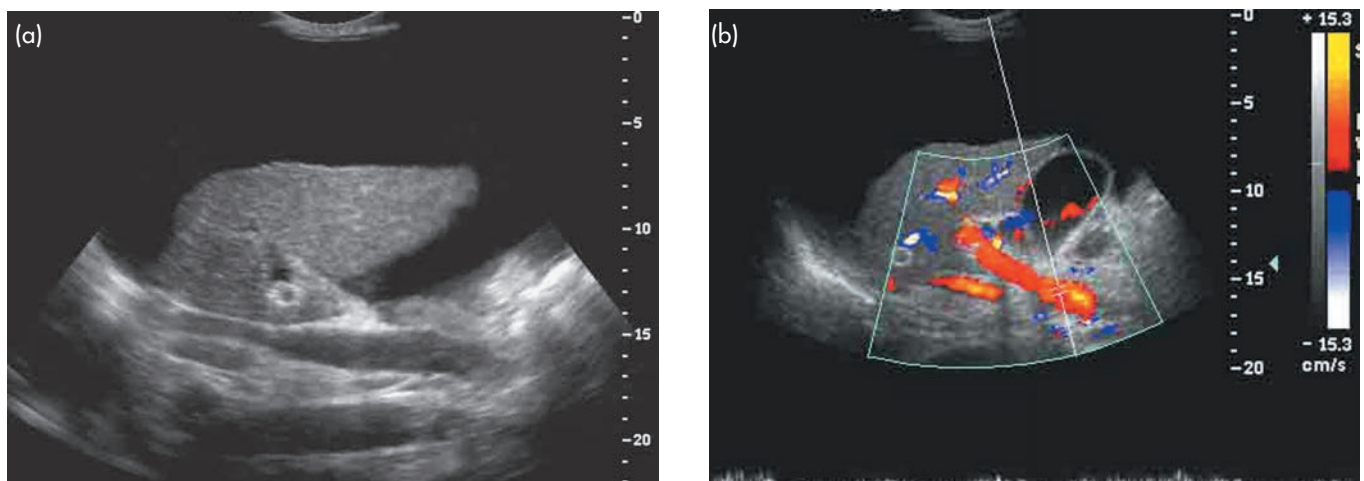

Figure 13.6 Sagittal ultrasound image of the liver (a) in a patient with cirrhosis demonstrates nodularity of the liver surface and extensive ascites. Doppler ultrasound (b) illustrates portal vein flow with a normal direction.

highly attenuated by air and bone and, thus, little information is gained with regard to tissues beyond bony or air-filled structures; alternative techniques may be required to image these areas (Summary box 13.4).

Summary box 13.4

Ultrasound

Strengths

- No radiation
- Inexpensive
- Allows interaction with patients
- Superb soft-tissue resolution in the near field
- Dynamic studies can be performed
- First-line investigation for hepatic, biliary and renal disease
- Endocavitary ultrasound for gynaecological and prostate disorders
- Excellent resolution for breast, thyroid and testis imaging
- Good for soft tissue, including tendons and ligaments
- Excellent for cysts and foreign bodies
- Doppler studies allow assessment of blood flow
- Good real-time imaging to guide interventional biopsies and drainages

Weaknesses

- Interpretation only possible during the examination
- Long learning curve for some areas of expertise
- Resolution dependent on the machine available
- Images cannot be reliably reviewed away from the patient

produce a two-dimensional grey-scale image of a slice through the body. This technique overcomes the problem of superimposition of different structures, which is inherent in conventional radiography. Improvements in gantry design, advances in detector technology using more sensitive detectors and an increase in the number of detectors have resulted in an increase in spatial resolution as well as the speed at which the images are acquired. In early CT scanners, the table on which the patient was positioned moved in between the gantry revolution to allow imaging of an adjacent slice. Modern scanners allow for continuous movement of the table and the patient during the gantry revolution, thus greatly reducing the scan time. With modern equipment, it is now not only possible to obtain images of the chest, abdomen and pelvis in under 20 seconds, but these axial images can be reformatted in multiple planes with practically no degradation in image quality.

In addition, CT has a far higher contrast resolution than plain radiographs, allowing the assessment of tissues with similar attenuation characteristics. As with radiographs, the natural contrast of tissues is further augmented by the use of intravenous

Figure 13.7 Ultrasound of the dorsal surface of the wrist shows the normal fibrillar pattern of the extensor tendons. There is increased fluid within the tendon sheath in this patient with extensor tenosynovitis.

Computed tomography

There has been a great deal of development in CT technology over the last 30 years from the initial conventional CT scanners through to helical or spiral scanners and the current multi-detector machines. CT scanners consist of a gantry containing the x-ray tube, filters and detectors, which revolve around the patient, acquiring information at different angles and projections. This information is then mathematically reconstructed to

Figure 13.8 Panoramic ultrasound of the calf. The normal muscle fibres and the fascia can be identified over an area measuring approximately 12 cm.

contrast medium. Rapid scanning of a volume of tissue also allows the scans to be performed at different phases of enhancement, which is advantageous in identifying different diseases. For instance, very early scanning during the arterial phase is ideally suited to the examination of the arterial tree and hypervascular liver lesions, whereas scanning performed after a delay may be better suited to the identification of other solid organ pathology such as renal masses. Furthermore, it is possible to obtain scans during several phases including the arterial and venous phases in the same patient, which may aid in the identification and characterisation of lesions.

CT is widely used in thoracic, abdominal (Figure 13.9), neurological (Figure 13.10), musculoskeletal (Figure 13.11) and trauma imaging. The thinner collimation and improved spatial resolution have also resulted in the development of newer techniques such as CT angiography, virtual colonoscopy and virtual bronchoscopy. Furthermore, three-dimensional images can be reconstructed from the raw data to aid in surgical planning. The disadvantage of CT compared with ultrasound and conventional

Figure 13.9 Axial computed tomography scan through the pelvis with oral contrast administration illustrates loops of distal ileum with mural thickening in a patient with Crohn's disease.

Figure 13.10 Axial computed tomography scan of the head following intravenous contrast demonstrates a large mass lesion in the left frontal region in a patient with a large left frontal meningioma.

radiography lies largely in the increased costs and the far higher doses of ionising radiation. For instance, a CT scan of the abdomen and pelvis has a radiation dose equivalent to approximately 500 chest radiographs (Summary box 13.5).

Summary box 13.5

Computed tomography

Strengths

- High spatial and contrast resolution
- Contrast resolution enhanced by imaging in arterial and/or venous phases
- Rapid acquisition of images in one breath-hold
- Imaging of choice for the detection of pulmonary masses
- Allows global assessment of the abdomen and pelvis
- Excellent for liver, pancreatic, renal and bowel pathology
- Three-dimensional reconstruction allows complex fracture imaging
- Multiplanar reconstruction and three-dimensional imaging, e.g. CT angiography and colonoscopy

Weaknesses

- High radiation dose
- Poor soft-tissue resolution of the peripheries and superficial structures
- Patient needs to be able to lie flat and still

Magnetic resonance imaging

Over the last 20 years, MRI has become an integral part of the imaging arsenal with ever-expanding indications. MRI relies on the fact that nuclei containing an odd number of protons or electrons have a characteristic motion in a magnetic field (precession) and produce a magnetic moment as a result of this motion. In a strong uniform magnetic field such as an MRI scanner, these nuclei align themselves with the main magnetic field and result in a net magnetic moment. A brief radiofrequency pulse is then applied to alter the motion of the nuclei. Once the

Figure 13.11 Coronal computed tomography (a) and axial reformat (b) of the foot in a patient involved in a road traffic accident demonstrates Lisfranc fracture dislocation with a comminuted fracture of the base of the second metatarsal.

radiofrequency pulse is removed, the nuclei realign themselves with the main magnetic field (relaxation) and in the process emit a radiofrequency signal that can be recorded, spatially encoded and used to construct a grey-scale image. The specific tissue characteristics define the manner and rate at which the nuclei relax. This relaxation is measured in two ways, referred to as the T1 and T2 relaxation times. The relaxation times and the proton density determine the signal from a specific tissue.

There are a large number of imaging sequences that can be used by applying radiofrequency pulses of different strengths and durations. The image characteristic and signal intensity from different tissues are governed by the pulse sequence employed and whether it is T1 weighted or T2 weighted. For instance, fat, methaemoglobin and mucinous fluid are bright on T1-weighted images, whereas water and thus most pathological processes, which tend to increase tissue water content, are bright on T2-weighted images. Cortical bone, air, haemosiderin and ferro-

magnetic materials are of very low signal on all pulse sequences. In general, T1-weighted images are superior in the delineation of anatomy, while T2-weighted images tend to highlight pathology better. For added tissue contrast, intravenous gadolinium may be administered. Other more specific contrast media are also available for liver, bowel and lymph node imaging.

MRI's exquisite contrast resolution, coupled with a lack of ionising radiation, is very attractive in imaging, particularly of tissues that have relatively little natural contrast. MRI also has the advantage of multiplanar imaging, as images can be acquired in any plane prescribed. It has traditionally been used extensively in the assessment of intracranial, spinal and musculoskeletal disorders (Figures 13.12, 13.13 and 13.14), allowing a

Figure 13.12 T2-weighted axial magnetic resonance imaging scan of the head in a patient with a large left-sided oligodendroglioma.

Figure 13.13 Sagittal T2-weighted magnetic resonance imaging scan of the lumbar spine demonstrates disc herniation in a patient with acute back pain.

Figure 13.14 Coronal magnetic resonance imaging scan of the knee demonstrating extensive serpiginous areas of altered signal intensity in the distal femur and proximal tibia in a patient with bone infarcts secondary to oral corticosteroids.

global assessment of bony and soft-tissue structures. More recent developments have resulted in new indications and applications. Today, MRI is commonly used in oncological imaging, such as staging of rectal carcinoma and gynaecological malignancies, identification and characterisation of hepatic masses, assessment of the biliary tree (magnetic resonance cholangiopancreatography (MRCP) (Figure 13.15)) and cardiac imaging. Techniques have also been developed which allow non-invasive angiography of the cranial and peripheral circulation (MR angiography) (Figure 13.16).

However, the availability of MRI is still relatively limited in comparison with other imaging techniques, and it is time-consuming with respect to image acquisition and interpretation. Images are easily degraded by motion, including respiratory and

Figure 13.15 Magnetic resonance cholangiopancreatography demonstrating dilated central intrahepatic bile ducts and a stricture of the common bile duct in a patient with obstructive jaundice and cholangiocarcinoma.

Figure 13.16 Maximum intensity projection image from a magnetic resonance angiogram demonstrating the abdominal aorta, common and external iliac arteries as well as parts of the pulmonary, mesenteric and renal vasculature.

cardiac motion. The use of respiratory and cardiac gating can minimise this, although bowel peristalsis can still be a problem. The long acquisition times require a cooperative patient who can lie very still, which can be difficult especially in claustrophobic individuals or those in pain. Furthermore, because of the use of high-strength magnetic fields, patients with some metallic implants, such as some aneurysm clips and prosthetic heart valves, and those with implanted electronic devices, such as pacemakers and defibrillators, cannot be examined. Some newer implants may, however, be MRI compatible, and patients with joint replacements can be studied safely (Summary box 13.6).

Nuclear medicine

In other imaging techniques using ionising radiation such as CT and conventional radiography, the individual is exposed to ionising radiation from an external source and the radiation transmitted through the patient is recorded. In nuclear medicine, however, a radioactive element or radionuclide such as technetium, gallium, thallium or iodine is administered to the patient as part of a radiopharmaceutical agent, and a detector such as a gamma camera is then used to record and localise the emission from the patient, thus forming the image. The radionuclide is chosen and coupled with other compounds such that it is distributed and taken up in the tissues of interest. Therefore, a variety of radionuclides are required for imaging of different tissues. Nuclear medicine also differs from other means of imaging, which are largely anatomically based, as it also provides functional information.

Radionuclide imaging is widely used in bone imaging with very high sensitivity for assessing metastatic disease, metabolic bone disease, established arthropathies and occult infection and traumatic injuries (Figure 13.17), although many of these applications are being replaced by MRI. In genitourinary disease, dynamic imaging can be performed to assess renal perfusion and function including obstruction, investigate renovascular hypertension and evaluate renal transplants. Radionuclide imaging

Summary box 13.6**Magnetic resonance imaging****Strengths**

- No ionising radiation
- Excellent soft-tissue contrast
- Best imaging technique for
 - Intracranial lesions
 - Spine
 - Bone marrow and joint lesions

Evolving use

- Staging
- MRCP
- MR angiography
- Breast malignancy
- Pelvic malignancy
- Cardiac imaging

Weaknesses

- Absolute contraindications
 - Ocular metallic foreign bodies
 - Pacemakers
 - Cochlear implants
 - Cranial aneurysm clips
- Relative contraindications
 - First trimester of pregnancy
 - Claustrophobia
- Long scan times so patients may not be able to keep still, especially if in pain
- Limited availability
- Expensive

Summary box 13.7**Radionuclide imaging****Strengths**

- Allows functional imaging
- Allows imaging of the whole body
- Bone scan has a high sensitivity for metastatic bone disease, fractures and infection
- PET scanning is valuable in the detection of metastatic cancer

Weaknesses

- Specific agents are required for specific indications
- Often non-specific and an abnormal result may require further imaging
- Generally poor spatial resolution

ultrasound has better resolution than MRI for small structures, with the added advantage of showing dynamic changes. CT enables visualisation of the fine detail of bony structures, clarifying abnormalities seen on plain radiographs (Summary box 13.8).

There are occasions when a combination of techniques will be important, and due consideration should be given to reducing the ionising radiation burden to the patient, using ultrasound and MRI as primary investigations whenever appropriate.

Summary box 13.8**Types of imaging**

- Radiographs are the best first-line test for bone lesions and fractures
- MRI is good for diagnosing bone marrow disease, occult fractures and tendon and soft-tissue disorders
- CT enables visualisation of the fine detail of bony structures
- CT gives the best three-dimensional information on fractures
- Ultrasound has better resolution in accessible soft tissues and can be used dynamically
- Ultrasound is the best method of distinguishing solid from cystic lesions
- Ultrasound is the only method for locating non-metallic foreign bodies
- Ultrasound is the best method for detecting muscle hernias

is also commonly used in thyroid and parathyroid disorders, ischaemic cardiac disease, detection of pulmonary emboli and assessment of occult infection and inflammatory bowel disease.

Positron emission tomography (PET) is an extension of nuclear medicine, in which a positron-emitting substance such as ^{18}F is tagged and used to assess tissue metabolic characteristics. The most commonly used radiolabelled tracer is ^{18}F -2-fluoro-2-deoxy-D-glucose (FDG), although other tracers can also be used in order to assess metabolic functions such as oxygen and glucose consumption and blood flow. Radioisotope decay causes the emission of a positron, which subsequently, within a few millimetres, collides with and annihilates an electron to produce a pair of annihilation photons. The drawbacks have been high cost, very limited availability and relatively low spatial resolution. The last of these has been addressed by PET/CT systems combining simultaneous PET imaging and CT, allowing the two sets of images to be registered so that the anatomical location of the abnormality can be localised more precisely (Summary box 13.7).

IMAGING IN ORTHOPAEDIC SURGERY**Introduction**

Imaging is an intricate part of musculoskeletal diagnosis, and image-guided, minimally invasive techniques also play a major role in treatment. In broad terms, radiographs are the best method of looking for bony lesions or injuries, MRI shows bone marrow disease, muscle tendon and soft-tissue disorders, and

Skeletal trauma

Musculoskeletal trauma is best imaged by an initial plain radiograph. All skeletal radiographs should be taken from two different angles, usually at right angles to each other. This is important in trauma because a fracture or dislocation may not be visible on a single view (Figure 13.18). Occasionally, and in specific locations such as the scaphoid, more than two views are routinely performed. If this fails to make a clear diagnosis, or if there is suspicion of soft-tissue injuries, then cross-sectional studies are indicated.

In the spine, CT is a normal second-line investigation, but this is best performed with reference to good-quality radiographs, including oblique views if necessary (Summary box 13.9).

Figure 13.17 Bone scintigraphy in a patient with carcinoma of the breast illustrating bony metastatic deposits involving multiple vertebrae, the skull, pelvis and ribs.

Figure 13.18 Anteroposterior radiograph of the wrist (a) in a patient following a fall does not show an acute bony injury. It is only on the second view (b) that a fracture of the dorsal cortex of the distal radius is visualised.

Summary box 13.9

Trauma imaging

- Initial imaging is radiography
- At least two views are needed
- Use CT for spine, intra-articular or occult fractures

Axial CT images alone may fail to diagnose some fractures, so three-dimensional reformatting is important to prevent errors. Sections should be thin, but care must be taken not to cover too wide an area, as the radiation burden may be excessive, particularly with multislice CT.

Degenerative disease

Synovitis

Radiographs are usually the first-line imaging investigation performed for the examination of joints. Typical changes of a degenerative or an erosive arthropathy are well known and understood. However, early arthropathy will be missed on radiographs and, with the advent of disease-modifying drugs, it is important to detect early synovitis before it is even apparent on clinical examination. Gadolinium diethyl triamine penta-acetic (DTPA)-enhanced MRI is the most sensitive method for detecting synovial thickening of numerous joints, but ultrasound is also sensitive, albeit more laborious to perform. Ultrasound shows effusions and synovial thickening clearly, and shows the

increased blood flow around the affected joints without the use of contrast agents (Figures 13.19 and 13.20).

Articular cartilage damage

Articular surface disease is difficult to detect using non-invasive techniques. MRI is probably the best method, although it is not sensitive to early chondral changes (Figure 13.21). Higher field strength magnets (3 Tesla and above) with dedicated surface

Figure 13.19 Axial T2-weighted fat-suppressed image of the wrist in a patient with rheumatoid arthritis demonstrating synovitis manifested as increased signal dorsal to the carpal bones.

Figure 13.20 Ultrasound of the wrist (a) shows thickening of tissues on the dorsal aspect of the radiocarpal joint. (b) There is increased flow on power Doppler ultrasound in this patient with wrist synovitis and rheumatoid arthritis.

Figure 13.21 Coronal magnetic resonance imaging of the knee demonstrates a focal osteochondral abnormality of the medial femoral condyle with full-thickness loss of the articular cartilage and abnormality of the subchondral bone.

coils provide more precise assessment; however, MR arthrography is currently the imaging 'gold standard'. Saline mixed with a dilute quantity of gadolinium DTPA is introduced into the joint by needle puncture, which is followed by an MRI examination. Using this technique, more subtle changes in the articular surface can be seen, including thinning, fissuring and ulceration. However, early softening of articular cartilage will not be visible. MR arthrography is also useful for detecting labral tears in the shoulder or hip (Figure 13.22), and in the assessment of patients who have undergone a previous meniscectomy. The triangular fibrocartilage of the wrist is also difficult to assess fully without arthrography (Figure 13.23).

In the shoulder, rotator cuff trauma and degenerative changes can be studied using ultrasound or MRI. In experienced hands,

Figure 13.22 Coronal oblique T1-weighted fat-suppressed image of the right shoulder following intra-articular injection of diluted gadolinium demonstrates imbibition of the gadolinium mixture into the superior labrum in a patient with superior labrum anterior posterior (SLAP) tear.

Figure 13.23 Coronal T1-weighted fat-suppressed image following injection of diluted gadolinium mixture into the radiocarpal joint shows extension of gadolinium into the distal radioulnar joint through a tear in the triangular fibrocartilage.

ultrasound has a higher accuracy rate, because image resolution is better and because the mechanical integrity of the cuff can be tested by dynamically stressing it (Figure 13.24). MRI has the advantage of being able to show abnormalities in the subcortical bone.

In the majority of arthropathies and degenerative disorders, serial imaging is useful. Changes in films taken weeks or months apart are far easier to see and interpret than from a single snapshot study (Summary box 13.10).

Summary box 13.10

Imaging techniques for joint disease

- Radiographs are good for assessing established articular disease
- Synovitis can be detected using ultrasound or contrast-enhanced MRI
- Early damage to articular cartilage is difficult to image by conventional methods
- Rotator cuff lesions are best studied using ultrasound or MRI
- Destructive lesions are best studied first on plain radiographs
- MRI is best for staging tumours
- Biopsy can be guided by fluoroscopy, CT or ultrasound

Aggressive bone disease

The radiograph is the first imaging technique for destructive lesions in bones. There is considerable experience in the interpretation of these films, especially with regard to whether the lesion is benign or malignant (Figure 13.25).

Radiographs are also vital in the assessment of soft-tissue calcification in tumours of muscle, tendon and subcutaneous fat. When a lesion is detected, there needs to be an early decision as to whether this is benign or malignant. If there is a suspicion of malignancy on the radiograph, or any uncertainty, then local staging is indicated. This is best performed by MRI for both bone and soft-tissue lesions (Figure 13.26). At this stage, it is

likely that a biopsy will be indicated, and preferably under image guidance. Soft-tissue and bone biopsy needles may be guided by CT, ultrasound or interventional MRI systems. The route of puncture should avoid vital structures and must be agreed with the surgeon, who will perform local excision if the lesion proves to be malignant. Care should be taken to avoid contaminating other compartments. In all circumstances, samples are best sent for both histopathological and microbiological examination. It may be difficult to tell on imaging whether or not a lesion is infected, and histology often provides a clear diagnosis in inflammatory conditions. Bone scintigraphy is useful in detecting whether a lesion is solitary or multiple, although whole-body MRI is becoming available (Summary box 13.11).

Summary box 13.11

Imaging of aggressive lesions in bone

- Plain radiographs are important as a first investigation
- MRI is best for local staging
- Bone scintigraphy or whole-body MRI for solitary or multiple lesion determination
- CT detects lung metastases
- Fluoroscopy, CT, MRI or ultrasound can be used to guide the biopsy

Mass lesions

Mass lesions in muscle and soft tissue are examined by ultrasound, which can be diagnostic in the majority of cases, thereby avoiding the need for further imaging. This is most often the case when a lesion is purely cystic and, as most soft-tissue masses are cysts, ultrasound is a very effective screening test. There are occasions when no mass lesion is found at the site of concern, and then reassurance can be offered. If the ultrasound examination is normal, this effectively excludes soft-tissue neoplasia. A reasonable protocol is to perform ultrasound on all palpable

Figure 13.24 Ultrasound of the supraspinatus tendon identifies a partial tear of the tendon, which is predominantly articular sided but with a component that is nearly full thickness.

Figure 13.25 Anteroposterior (a) and lateral (b) radiographs of the left knee in a young patient with knee pain. There is a mixed lucent and sclerotic lesion of the distal femur with breach of the cortex medially and soft-tissue extension seen anteriorly and posteriorly. The location and appearances are consistent with osteosarcoma.

'lesions' to exclude cysts, and on patients without any identifiable mass, and to proceed to MRI only when there is a solid or partly solid element to an unidentifiable lesion. Tumour vascularity is best assessed by Doppler ultrasound. It can be studied by intravenous gadolinium DTPA-enhanced MRI; however, this is a more expensive and invasive technique, providing no more information than Doppler ultrasound (Summary box 13.12).

Summary box 13.12

Imaging of soft-tissue lesions

- Ultrasound is the best for screening; it is often the only imaging required
- MRI is best for local staging and follow up
- Doppler ultrasound can assess vascularity cheaply and effectively
- Ultrasound is useful for biopsy

Figure 13.26 Coronal T1- (a) and axial T2-weighted fat-suppressed (b) images through the distal femur of the patient in Figure 13.25 illustrates the bony area involved, the soft-tissue extent of the tumour and the relationship of the neurovascular structures to the mass.

Infection

In the early stages of joint infection, the plain films may be normal, but they should still be performed to exclude bony erosions, in case a painful joint is the first sign of an arthropathy. Ultrasound examination is the easiest and most accurate method of assessing joint effusions, although, when an effusion is identified, it is not possible to discriminate between blood and pus. Aspiration guided by ultrasound is the best method of making this distinction. MRI may be required to assess early articular cartilage and bone involvement.

Radiographs should also be used to examine patients with suspected osteomyelitis. Although they may not detect early infection, they will demonstrate or exclude bony destruction, calcification and sequestrum formation. CT may be needed to give a cross-sectional view, in order to assess the extent of bony sequestrum.

MRI is perhaps the most sensitive method for detecting early disease and is the preferred technique to define the activity and extent of infection, as it shows not only the bony involvement but also the extent of oedema and soft-tissue involvement (Figure 13.27). Abscesses may be detected or excluded, and subperiosteal oedema is readily visible. MRI can be used as a staging procedure to plan treatment, including surgical intervention. Serial examinations can be used to follow the response to intravenous antibiotics and are very useful in the management of complex osteomyelitis. In cases of negative or equivocal MRI, nuclear medicine techniques such as bone scintigraphy can be very sensitive, and specialised studies using tracers such as gallium citrate or indium-labelled white cells increase specificity (Summary box 13.13).

Summary box 13.13

Imaging of potentially infected bone and joint

- Plain radiographs may be needed to exclude bone erosion
- Ultrasound is sensitive for an effusion, periosteal collections and superficial abscesses and can be used for guided aspiration
- CT is useful in established infection to look for sequestrum
- MRI is useful to define the activity of osteomyelitis, early infection and soft-tissue collections
- Bone scans are sensitive but of low specificity
- Complex nuclear medicine studies are useful in negative MR examinations or equivocal cases

Figure 13.27 (a) The plain films of this 13-year-old are close to normal. On close inspection, there is a fine periosteal reaction on the fibula. (b) The coronal T1-weighted magnetic resonance image shows little more, but (c) the coronal fast STIR (short tau inversion recovery) images and (d) axial T2 fast spin echo with fat suppression show the oedema in bone as white and the extensive periosteal fluid with soft-tissue inflammation. The diagnosis is acute osteomyelitis.

Metabolic bone disease

Plain radiographs should be the first images of patients with metabolic bone disease. They may detect the subperiosteal erosions in hyperparathyroidism or, more commonly, the osteopenia in osteoporosis, but they cannot be used to quantify osteoporosis. The apparent density of the bone on the film is linked to the penetration of the rays, among other variables, as well as to the bone density. If a quantitative method is needed, however, bone mineral density using dual x-ray absorptiometry (DEXA) is the most accurate and practical. However, fractures will cause erroneously high readings, and they tend to occur in the vertebrae used for DEXA measurements. Quantitative CT is an alternative technique, although this is less readily available. Ultrasound transmission measurement in the extremities has its advocates, as it arguably measures factors that better represent the strength of bone rather than its density. Its limitations are that it cannot be used to study the vertebrae or hip, and these are the sites where osteoporotic fractures occur most frequently. MRI may be useful in detecting fractures and is an essential prerequisite to percutaneous vertebroplasty.

IMAGING IN MAJOR TRAUMA

Introduction

Trauma remains a major cause of mortality and morbidity in all age groups. Presented with a multiply injured patient, rapid and effective investigation and treatment are required to maximise the chances of survival and to reduce morbidity. Imaging plays a major role in this assessment and in guiding treatment. As with the clinical assessment, imaging is carried out according to the principles of primary and secondary surveys, identifying major life-threatening injuries of the airway, respiratory system and circulation before a more detailed and typically time-consuming assessment of other injuries. At no point should imaging delay the treatment of immediately life-threatening injuries. As in other settings, the quickest and least invasive examinations should be performed first. A radiologist present in the trauma room at the time of patient assessment is able to rapidly evaluate the radiographs, relay this information back to the team and guide further imaging, which may include further plain films, CT, ultrasound and MRI.

Plain radiographs

Conventional radiography allows rapid assessment of the major injuries and can be carried out in the trauma room while the patient is clinically assessed and treated. Despite the time constraints, the number of staff involved and the restricted mobility of the patient, high-quality images can be routinely obtained with due care and attention.

There is no routine set of radiographs to be obtained, and the decision is based on the mechanism of injury, the stability of the patient's condition and whether the patient is intubated. The most commonly performed initial radiographs are a chest radiograph, a single anteroposterior view of the pelvis and a cervical spine series.

The supine chest radiograph should encompass an area from the lung apices to the costophrenic recesses and include the ribs laterally. Chest radiographs give valuable information in both blunt and penetrating trauma. Evaluation of the radiograph should be undertaken in a systematic manner to minimise the

chances of missing an injury. In the first instance, the position of line and tubes including the endotracheal tube should be assessed followed by assessment of the central airways. Following this, the lungs should be evaluated for abnormal focal areas of opacification, which may represent aspiration, haemorrhage, haematoma or oedema as well as more diffuse opacification reflecting a pleural collection. Alternatively, relative focal or unilateral lucency may reflect a pneumothorax in the supine position. Evaluation of the mediastinum should include its position, which may be altered by tension pneumothoraces or large collections, as well as its contour, an alteration of which may reflect a mediastinal haematoma due to aortic or spinal injury. Finally, the skeleton and the soft tissue should be carefully examined for rib, vertebral, scapular and limb fractures as well as evidence of surgical emphysema and paraspinal haematomas (Figure 13.28).

Pelvic radiographs are also commonly performed to screen for and assess fractures of the bony pelvis. The image should include the iliac crests in their totality and extend inferiorly to below the lesser trochanters. When assessing the film, the alignment of the sacroiliac joints and the symphysis pubis should be carefully examined, as some fractures, especially those of the sacral arcades, can be very subtle on the pelvic radiograph. The presence of pubic fractures raises the possibility of urethral injury and should alert clinicians to exercise caution with bladder catheterisation (Figure 13.29).

The utility of cervical spine x-rays depends on the consciousness level of the patient and the presence of distracting injuries. In fully conscious patients with an isolated neck injury, clinical assessment can be used to guide the need for x-rays. In patients with distracting injuries and/or altered consciousness, including intubated patients, radiography is required. Typically, in patients who are not intubated, at least three views are performed including an anteroposterior view, an open mouth odontoid peg view and a lateral view extending down to the cervicothoracic

Figure 13.28 Supine chest radiograph of a patient involved in a road traffic accident. The patient is intubated. There are multiple left-sided rib fractures and extensive surgical emphysema. Depression of the left hemidiaphragm and mediastinal shift to the right suggest that there is a tension pneumothorax present.

Figure 13.29 Retrograde urethrogram in a patient who sustained extensive pelvic fractures following a fall. The pelvic injuries have been stabilised using an external fixation device. The urethrogram identifies extensive injury to the urethra with extravasation of contrast.

junction. These may be supplemented with trauma oblique views in which the tube is rotated rather than the patient. In intubated individuals, open mouth views cannot be performed, and soft-tissue assessment is impaired by the presence of the endotracheal tube, so CT should be used to supplement an initial lateral radiograph (Figure 13.30). When fractures are identified or when the radiographs do not fully examine the cervicothoracic junction, CT is indicated. If the patient is to undergo emergency CT examination for head or chest indications, a good-quality multidetector CT study using thin sections and both coronal and sagittal reconstructions may be used to replace radiographs. CT may also be indicated when the radiographs appear normal but the nature of the injury or the clinical circumstances strongly suggest that the cervical spine may be injured.

Further radiographs of the thoracic and lumbar spine and the peripheral skeleton may be required depending on the clinical setting. As with all skeletal radiographs, two perpendicular views are required for adequate assessment. Radiographs of the skull or facial bones have no role in the immediate assessment of the multitrauma individual except for immediate localisation of a penetrating object.

Ultrasound

Ultrasound has an evolving role in the assessment of acutely traumatised patients. The main current roles of ultrasound include the assessment of intraperitoneal fluid and haemopericardium (focused assessment with sonography for trauma, FAST), the evaluation of pneumothoraces in supine patients and in guiding intervention.

FAST ultrasound is a limited examination directed to look for intraperitoneal fluid or pericardial injury as a marker of underlying injury. This avoids the invasiveness of diagnostic peritoneal lavage. In the presence of free intraperitoneal fluid and an unstable patient, the ultrasound allows the trauma surgeon to explore the abdomen as a cause of blood loss. In the presence of fluid and a haemodynamically stable individual, further assessment by way

Figure 13.30 Lateral view of the cervical spine (a) fails to demonstrate the cervicothoracic junction. In addition, there appears to be a break in the posterior arch of C1. Computed tomography of the cervical spine (b) demonstrated a fracture of the anterior arch as well as the posterior arch of C1.

of CT can be performed. However, it is important to realise that ultrasound has limitations in the identification of free fluid. This includes obscuration of fluid by bowel gas or extensive surgical emphysema. More organised haematoma may be more difficult to visualise. It must also be emphasised that the principal role of ultrasound is not to identify the primary solid organ injury, although this may be visualised. Occasionally, a second ultrasound scan may show free fluid in the presence of an initially negative FAST scan.

The detection of a pneumothorax on a supine radiograph can be very difficult. Ultrasound examination may be used to identify a radiographically occult pneumothorax. With a high-resolution linear probe, the pleura can be visualised as an echogenic stripe,

Figure 13.31 Computed tomography of the head in a patient with head injury shows bilateral large frontal extradural collections.

and its motion with respiration can also be assessed. In the presence of a pneumothorax, the sliding motion of the pleura is lost. Ultrasound may also be used to detect a haemothorax or haemopericardium.

Finally, ultrasound may be of value in guiding the placement of an intravascular line by direct visualisation of the vessels. This can be especially advantageous in shocked patients.

Computed tomography

CT is the main imaging method for the investigation of intracranial and intra-abdominal injuries and vertebral fractures. With current multidetector scanners a comprehensive examination of the head, spine, chest, abdomen and pelvis can be completed in less than 5 minutes. However, much more time is taken up in transferring the patient and the associated monitoring equipment onto the scanner. Therefore, the total time can be in excess of 30 minutes, and CT should be reserved for individuals whose condition is stable.

CT examination of the head is accurate in identifying treatable intracranial injuries (Figures 13.31 and 13.32) and should not be delayed by radiography of peripheral injuries, as there is declining success in cases of intracranial collection when treated after the initial 3–4 hours. In comparison, identification of more widespread injuries, such as diffuse axonal injury, is relatively poor. Examination of facial injuries and cervical spine fractures can also be carried out at the same time as this only adds seconds to the examination. There is evidence that CT of the abdomen and pelvis is of benefit in multiple trauma when there is a head injury, as it often shows unexpected abnormalities, and this may affect the immediate management, especially if the patient deteriorates.

Chest CT with intravenous contrast agent is valuable in identifying vascular and lung injuries and is the most accurate

Figure 13.32 Computed tomography of the head following head trauma shows a skull fracture with a large depressed component.

way of demonstrating haemothorax and pneumothorax. The position of chest drains can be identified, allowing adjustment of position if necessary. Abdominal and pelvic CT is usually undertaken as an extension to the chest CT. If an abdominal examination is performed, the pelvis should be included to avoid missing pelvic injuries and free pelvic fluid. CT is an excellent means of identifying hepatic, splenic (Figure 13.33) and renal injuries. Delayed examination after the administration of intravenous contrast agents allows assessment of the pelvicalyceal system in cases of renal trauma. Pancreatic and duodenal injuries may also be identified, but detection of these injuries may be more problematic. Using CT, the accuracy of detection of bowel or mesenteric injuries is less than it is for solid organ injury, and these injuries should be suspected when there is free intraperitoneal fluid without an identifiable cause (Figure 13.34).

Figure 13.33 Post-contrast abdominal computed tomography of a patient following blunt abdominal trauma shows a splenic laceration with herniation of mesenteric fat. A right-sided pleural collection is also evident.

Figure 13.34 Post-intravenous contrast computed tomography examination in a patient with a penetrating abdominal injury and mesenteric tear shows free fluid in the flanks and active extravasation of contrast centrally.

The image data may be reconstructed into thinner slices for the diagnosis of injuries to the thoracic and lumbar spine and for the better delineation of pelvic and acetabular fractures. Multidetector machines will be optimal for this purpose but, with older CT scanners, additional dedicated thin sections may be required for adequate examination. Complex intra-articular fractures of the peripheral skeleton, such as calcaneal and tibial plateau fractures, may be usefully examined by dedicated thin-section studies provided this does not delay the treatment of other more serious injuries (Figure 13.35). CT angiography may be used to demonstrate vascular injuries in the limbs in those with penetrating injuries or complex displaced fractures.

Magnetic resonance imaging

The value of immediate MRI in trauma is relatively limited and is largely confined to the imaging of spinal injuries (Figure 13.36).

Figure 13.35 Sagittal reformats of computed tomography of the calcaneus in a patient following a fall illustrate a comminuted calcaneal fracture with intra-articular extension into the posterior facet of the subtalar joint.

Figure 13.36 Sagittal T1-weighted (a) and T2-weighted (b) magnetic resonance imaging of the spine demonstrates a burst fracture of L2 causing neural compression.

Access to urgent MRI is not widely available, and there are major practical problems in imaging patients who require ventilation or monitoring. MRI is therefore only practical in stable patients. All monitoring equipment must be MRI compatible, and ventilation support should be undertaken by staff skilled and experienced in these techniques as applied to the MRI environment. MRI may be used to diagnose injuries of the spinal cord and associated perispinal haematomas in patients with neurological

signs or symptoms. MRI can supplement CT in spinal injuries by imaging soft-tissue injuries to the longitudinal and interspinous ligaments. MRI is mandatory in patients in whom there is facet dislocation if surgical reduction is being considered to minimise the risk of displacing soft-tissue or disc material into the spinal canal during reduction procedures. Subtle fractures may be difficult to identify, particularly if they are old, but an acute injury is normally identified by the surrounding oedema. Bony abnormalities should be reviewed using CT, as fracture lines are hard to identify with MRI and unstable injuries may be overlooked. In the less acute setting, MRI may also be used to assess diffuse axonal injuries, with an accuracy exceeding CT.

Vascular interventional radiology

Angiography has been used for both the diagnosis and treatment of vascular injuries in the trauma patient. With the development and refinement of CT angiography techniques, the diagnostic role of interventional radiology may become more limited. Already, CT has a diagnostic accuracy similar to that of formal angiograms in patients with suspected aortic injuries, with the latter reserved for cases where CT has been suboptimal, doubt exists about the diagnosis or stent grafting is being considered. At present, peripheral angiograms are still performed, particularly in cases of penetrating injury, but as experience grows with CT peripheral angiography, this will probably become the preferred technique.

Endovascular techniques play an important role in the treatment of acute solid organ injuries, and the interventional radiologist should be consulted early in the decision-making process. Using coaxial catheter systems and a variety of available embolic agents such as soluble gelatine sponge and microcoils, selective embolisation and reduction of blood flow to the injured segment can be achieved without causing infarction. Selective embolisation techniques are also suitable for the treatment of patients with pelvic fractures with ongoing blood loss and volume issues. With penetrating and non-penetrating extremity trauma, balloon occlusion and embolisation may be employed to control haemorrhage, while the application of stent grafts can aid in re-establishing the circulation to the affected extremity.

IMAGING IN ABDOMINAL SURGERY

The acute abdomen

The term 'acute abdomen' encompasses many diverse entities.

IMAGING IN COMMON SURGICAL CLINICAL SCENARIOS

In this section the roles of different radiological modalities in common surgical scenarios are discussed with a brief rationale behind their use and typical appearances of various pathological processes.

Bowel obstruction

The plain abdominal radiograph is a useful tool in diagnosing bowel obstruction. Small bowel obstruction can generally be distinguished from large bowel obstruction by virtue of the following: small bowel lies centrally in the abdomen while large bowel lies peripherally, the valvulae conniventes (folds) of the small bowel traverse the entire width of the lumen while the

haustra of the large bowel do not, and the calibre of the small bowel is typically less than the large, even when obstructed (typical measurements in obstruction: small bowel 3.5–5 cm, large bowel 5–8 cm).

However, it must be stressed that a normal plain radiograph does not exclude an obstruction and if there is persistent concern further imaging is indicated and CT is the modality of choice having largely superseded the contrast follow-through or enema, particularly in the acute setting. The key to diagnosis of a mechanical obstruction of either small or large bowel on CT, and differentiation from paralytic ileus, is identification of a transition zone from dilated proximal bowel to collapsed distal bowel. In small bowel obstruction if no obvious cause such as a mass, volvulus or intussusception is identified, then the most likely aetiology is adhesional. There is no need to give oral contrast for a suspected bowel obstruction CT as fluid in the lumen is a natural contrast agent and in any case oral contrast may well not reach the point of obstruction by the time of the scan. CT is also invaluable to diagnose complications of bowel obstruction such as perforation and ischaemia.

Perforation

The erect chest x-ray (CXR) is the ideal first test for hollow organ perforation and as little as 10–20 mL of free air can be detected under the diaphragm, with the following caveats (Figures 13.37 and 13.38): about 10 minutes should be left between sitting the patient upright to allow air time to rise, the free air must be sought under the right hemidiaphragm to prevent misinterpretation of the gastric air bubble and the reviewer must be able to recognise Chilaiditi's syndrome, the harmless and asymptomatic interposition of large bowel between the liver and diaphragm. Caution must also be exercised in interpreting any free air in the context of recent abdominal surgery as air can persist for up to 5–7 days in the peritoneal cavity.

If the erect CXR is equivocal or a possible walled-off perforation is suspected, a CT is the optimal modality, which may show tiny quantities of free air but may also show the cause,

Figure 13.37 Erect chest radiograph showing marked bilateral elevation of the hemidiaphragms with a large volume of subdiaphragmatic free gas.

Figure 13.38 Pneumoperitoneum. The presence of free intraperitoneal air outlines the bowel so that both sides of the bowel wall can be seen (Rigler's sign).

e.g. peptic ulcer, diverticulitis or a neoplastic lesion. As with suspected obstruction, oral or rectal contrast is unnecessary if perforation is suspected as making the diagnosis should prompt appropriate management even if the precise site of perforation is not identified. Also, it cannot be overstressed that if there is any possibility of a leak from the gastrointestinal tract (including an anastomotic leak after surgery), then the use of barium is absolutely contraindicated as it can induce a serious and potentially fatal peritonitis.

Ischaemia/infarction

The most useful test when bowel ischaemia or infarction is suspected is a CT scan. Intravenous contrast administration is essential to look for thrombus/embolus in the mesenteric vessels, though ischaemia due to low flow states can still occur in their absence. Ischaemia can be a difficult diagnosis to make radiologically but is suspected, in the appropriate clinical context, by bowel wall thickening, submucosal oedema and free fluid between the folds of the mesentery (particularly if haemorrhagic). Ischaemia must be strongly suspected if these findings are seen in association with a closed loop obstruction or strangulated hernia. Ischaemic colitis typically affects the 'watershed area', which is the junction of the areas supplied by the superior and inferior mesenteric arteries, typically in the region of the splenic flexure.

When bowel wall ischaemia proceeds to transmural infarction, the diagnosis is usually more straightforward with evidence of pneumatosis (air in the bowel wall) typically identified. The

air in the bowel wall can then track into mesenteric veins and thence to the portal vein, a CT sign of grave prognostic significance in an adult as it implies widespread and relatively long-standing bowel infarction.

Gastrointestinal haemorrhage

The aetiology of acute gastrointestinal haemorrhage varies between the upper gastrointestinal tract (GIT) (common causes including peptic ulcer disease, varices and Mallory Weiss tears) and the lower GIT (common causes including angiodysplasia, diverticular haemorrhage and neoplastic lesions). While endoscopy is a useful first-line investigation for both, in refractory or occult gastrointestinal (GI) haemorrhage radiology can also contribute to diagnosis and management. Nuclear medicine scans using radioisotope-labelled red blood cells are useful when bleeding is intermittent. An increasingly popular investigation is a CT mesenteric angiogram. Non-contrast scans to look for bright blood in the bowel lumen should be supplemented with scans in the arterial phase to assess for a blush due to active extravasation, and portal venous phase to optimise detection of wall thickening and masses and to look for sites of venous bleeding. If non-invasive imaging is effective, catheter angiography can be used to embolise a bleeding point, though it is occasionally used as a diagnostic test should other tests be negative.

Inflammatory processes

Appendicitis

Historically, a straightforward clinical diagnosis of appendicitis obviated any need for imaging, but with the proven accuracy of available modalities imaging has become increasingly popular to reduce negative appendectomy rates and to make alternative diagnoses. While a plain radiograph may demonstrate a calcified appendicolith in the right iliac fossa, it is insufficiently sensitive or specific to be reliable. In children ultrasound is the best test, to reduce radiation exposure and due to typically favourable body habitus. This also applies to females of childbearing age, again to reduce radiation exposure, but also as the symptoms may be mimicked by gynaecological pathology, such as ectopic pregnancy, haemorrhagic ovarian cyst and tubo-ovarian abscess, all diagnoses best made with ultrasound. The definitive exclusion of appendicitis, however, hinges on the identification of a normal appendix, measuring less than 6 mm diameter. Retrocaecal appendicitis can readily escape detection with ultrasound and thus CT is the next modality of choice and indeed frequently the first requested in most adults (Figure 13.39). The diagnosis of appendicitis on CT requires the identification of a thickened appendix (>7 mm), with periappendiceal inflammatory change as evidenced by stranding in the surrounding fat. Other signs which may be sought include free fluid, thickening of the caecal pole, possible localised small bowel ileus and right iliac fossa lymphadenopathy. Both CT and ultrasound can also identify collections if an inflamed appendix ruptures and can be used to guide percutaneous drainage as a bridge to definitive surgery.

Diverticulitis

Inflammation of an obstructed diverticulum typically presents with left iliac fossa pain and pyrexia (Figure 13.40). While some authors have promoted the use of focused ultrasound for this indication, in general it is best diagnosed with a CT scan. The typical CT appearance is of pericolic inflammatory change

Figure 13.39 Computed tomography scan. Acute appendicitis. Note the thickening of the caecal wall with a periappendiceal fluid collection indicating an appendix abscess.

Figure 13.40 Computed tomography scan showing a segment of thickened sigmoid colon with a paracolic abscess (arrow) in a patient with diverticulitis.

around a diverticulum, most commonly in the sigmoid colon. Complications of diverticulitis include perforation, abscess formation, fistulation to adjacent structures and strictures in the bowel; CT is also the modality of choice to identify these, and as with appendicitis can be used to guide percutaneous abscess drainage as a bridge to definitive surgery (Figure 13.41).

Inflammatory bowel disease

The diagnosis of inflammatory bowel disease is made histologically though a barium study of the small bowel, either a follow-through (where barium is ingested orally) or enteroclysis (where dilute barium is infused via an NJ tube) is often used as a screening tool if symptoms are vague. If the diagnosis of Crohn's disease is established, barium studies are useful to demonstrate the extent of disease, particularly to demonstrate the length and

Figure 13.41 High-grade small bowel obstruction due to adhesions. Computed tomography scan showing multiple, dilated, fluid-filled loops of small bowel with collapsed distal ileal loops beyond the point of obstruction (arrow).

number of strictures if surgery is planned, although increasingly this role is being superseded by MRI enterography, which entails an abdominopelvic MRI scan after ingestion of an agent such as lactulose or mannitol to distend the small bowel. The other obvious advantage of MRI is the lack of radiation, particularly relevant in young patients with Crohn's disease who often undergo multiple imaging studies over their lifetime, and for this reason it is gaining in popularity for inflammatory bowel disease follow up.

An acute flare up may also require imaging, and an ultrasound is usually a good first test to look for dilated bowel loops and any abscess, though CT may ultimately be required as gas-filled bowel loops can obscure visualisation of an abscess on ultrasound. MRI is the imaging modality of choice to assess perianal fistulae and abscesses.

Acute pancreatitis

As with acute appendicitis, when the diagnosis is straightforward clinically there may be no need for imaging, though increasingly it is used to confirm the diagnosis, to assess the severity of the process and to look for complications. While ultrasound may show gallstones and can demonstrate an enlarged pancreas with peripancreatic fluid and inflammatory changes, the optimal modality is CT. CT performed too early in the course of the attack, e.g. in the first 12 hours, can be equivocal and the optimal timing of imaging is 48–72 hours.

In mild acute pancreatitis, CT may be normal or may show an enlarged oedematous gland, but in more severe attacks other findings which should be sought include peripancreatic fluid collections, vascular complications such as arterial pseudoaneurysm formation or venous thrombosis and necrosis either of the gland itself or of the surrounding fat. Necrosis typically develops 48–72 hours after the onset of symptoms, and is manifest on CT as lack of enhancement of the necrotic areas.

CT with intravenous contrast is therefore essential to look for necrosis, which is potentially catastrophic particularly if it becomes infected. While CT is not always reliable to diagnose infected necrosis it is suggested by bubbles of air in the necrotic segment. As with other intra-abdominal inflammatory processes, either ultrasound or more usually CT can be used to guide percutaneous drainage of inflammatory fluid collections.

Acute cholecystitis/biliary colic/jaundice

While acute cholecystitis is usually due to mechanical obstruction of the cystic duct or gallbladder neck by a gallstone, acute acalculous cholecystitis can occur in critically ill patients from a number of causes. In any case ultrasound is the modality of choice should this diagnosis be suspected, and the classic diagnostic features are of gallbladder distension with wall thickening (>3 mm). A gallstone obstructing the gallbladder neck or cystic duct may be visualised; alternatively, in acalculous cholecystitis sludge may be seen layering in the gallbladder lumen. Associated signs include pericholecystic fluid and hyperaemia on Doppler examination. Ultrasonographic Murphy's sign refers to tenderness over the gallbladder when pressure is applied while scanning and is a supportive finding in making the diagnosis. As a second-line investigation CT is also accurate for this condition, demonstrating similar signs of gallbladder distension and wall thickening with surrounding inflammatory changes. CT is also useful to diagnose complications such as gangrenous cholecystitis, gallbladder perforation and emphysematous cholecystitis, which may necessitate emergency cholecystectomy. If cross-sectional studies are equivocal, hepatobiliary scintigraphy can be useful, with the diagnosis of acute cholecystitis suggested by non-visualisation of the gallbladder 3 hours after radioisotope administration.

A frequent limitation of ultrasound is failure to visualise the common bile duct throughout its length due to overlying bowel gas, and elective cholecystectomy was typically accompanied by bile duct exploration to look for duct calculi. Increasingly, however, MRCP has been shown to be highly accurate in excluding bile duct calculi before surgery.

Ultrasound is also a useful first-line investigation for jaundice of unknown cause as it can demonstrate duct dilatation and gallstones. If a definitive cause is not shown with ultrasound, or a mass is identified but its precise nature and extent is uncertain, CT is indicated to look for common causes including stones, cholangiocarcinoma and pancreatic carcinoma. CT can not only identify malignant lesions but can also demonstrate the extent of local infiltration and the presence of metastases to determine potential resectability. If the ducts are of normal calibre in a jaundiced patient, liver biopsy should be considered.

Renal colic

The historical methods of imaging for renal colic all have their limitations. Plain film radiography may not demonstrate all calculi, will not show renal tract obstruction and is unreliable for alternative diagnoses. IVU necessitates the administration of intravenous contrast and, if a level of obstruction is sought, delayed films up to 8 hours after injection may be required; it also will not provide alternative diagnoses. Ultrasound will demonstrate hydronephrosis and hydroureter, and calculi in the kidneys and either the proximal or distal ureters can usually be identified as echogenic foci with posterior acoustic shadowing; however, the ureter from just below the kidneys to the pelvis is

usually obscured by bowel gas which significantly impairs stone detection.

For these reasons the optimal investigation is now CT KUB, a non-contrast, low dose (2–3 MSv if a low mA scan is performed, equivalent to the dose from a limited IVU series) scan from the upper poles of the kidneys to the pubic symphysis. Contrast administration, either orally or intravenously, is not employed as it does not aid stone detection and may even impair it. Stones are readily identified as high attenuation (typically calcific) foci, and the secondary signs of acute ureteric obstruction may also be seen, including hydronephrosis and hydroureter, renal enlargement and perinephric fat stranding. The most common sites for stones to be seen are at the areas of ureteric narrowing, namely the pelvi-ureteric junction, the pelvic brim and vesico-ureteric junction. CT also offers unrivalled capability for making alternative diagnoses when compared with other modalities.

Abdominal aortic aneurysm

If a pulsatile mass is felt in the abdomen and the diagnosis of a possible abdominal aortic aneurysm (AAA) is suspected, ultrasound is a useful modality and provided the aorta is not obscured by bowel gas an aneurysm can usually reliably be excluded. If, however, ultrasound visualisation is suboptimal and the diagnosis is as a result equivocal, or if an aneurysm is identified and information regarding the extent and exact size is required, for example for surgical or endovascular repair planning, CT angiography is indicated, with the aorta typically scanned from the arch to the pubic symphysis in the arterial phase after intravenous contrast. MR angiography is a useful alternative if iodinated contrast is contraindicated.

In the case of suspected aneurysm rupture, provided the patient is sufficiently haemodynamically stable to undergo CT, CT angiography should be urgently performed and supplemented by a non-enhanced initial scan which is useful to look for retroperitoneal haematoma, which is typically of relatively high attenuation compared to the blood in the lumen on a non-contrast scan.

IMAGING IN ONCOLOGY

Modern surgical treatment of cancer requires an understanding of tumour staging systems, as in many instances the tumour stage will define appropriate management. The development of stage-dependent treatment protocols involving neoadjuvant chemotherapy and preoperative radiotherapy relies on the ability of imaging to determine stage accurately before surgical and pathological staging. Once a diagnosis of cancer has been established, often by percutaneous or endoscopic biopsy, new imaging techniques can considerably improve the ability to define the extent of tumour, although the pathological specimen remains the 'gold standard'. Many staging systems are based on the tumour–node–metastasis (TNM) classification.

Tumour

In most published studies, cross-sectional imaging techniques (CT, ultrasound, MRI) are more accurate in staging advanced (T3, T4) than early (T1, T2) diseases, and the staging of early disease remains a challenge. In gut tumours, endoscopic ultrasound is more accurate than CT or MRI in the local staging of early disease (T1 and T2) by virtue of its ability to demonstrate the layered structure of the bowel wall and the depth of tumour

Figure 13.42 (a) Echo endoscopy in gastric cancer. The hypoechoic tumour (arrows) is destroying the layered structure of the gastric wall and extending out beyond the serosa. (b) Computed tomography scan demonstrates thickening and enhancement of the gastric wall in the same area (arrows). The stomach is distended with water to provide low-density contrast.

penetration (Figure 13.42). Developments in MRI may also improve the staging accuracy of early disease. MRI is extremely valuable in bone and soft-tissue tumour staging and in intracranial and spinal disease.

Nodes

Accurate assessment of nodal involvement remains a challenge for imaging. Most imaging techniques rely purely on size criteria to demonstrate lymph node involvement, with no possibility of identifying micrometastases in normal-sized nodes. A size criterion of 8–10 mm is often adopted, but it is not usually possible to distinguish benign reactive nodes from infiltrated nodes. This is a particular problem in patients with intrathoracic neoplasms, in whom enlarged benign reactive mediastinal nodes are common. The echo characteristics of nodes at endoscopic ultrasound have been used in many centres to increase the accuracy of nodal staging, and nodal sampling is possible via either mediastinoscopy or transoesophageal biopsy under endoscopic ultrasound control. New radioisotope techniques are being developed using radiolabelled monoclonal antibodies against tumour antigens, which may increase the detection of nodal involvement by demonstrating micrometastases in non-enlarged nodes. There are current clinical studies of new MRI contrast agents that may identify tumour-infiltrated nodes.

Metastases

The demonstration of metastatic disease will usually significantly affect surgical management. Modern cross-sectional imaging has greatly improved the detection of metastases, but occult lesions will be overlooked in between 10 and 30 per cent of patients. CT is the most sensitive technique for the detection of lung deposits,

although the decision to perform CT will depend on the site of the primary tumour, its likelihood of intrapulmonary spread and the effect on staging and subsequent therapy of the demonstration of intrapulmonary deposits.

Ultrasound and CT are most frequently used to detect liver metastases. Contrast-enhanced CT can detect most lesions greater than 1 cm, although accuracy rates vary with the technique used and range from 70 to 90 per cent. Recent studies suggest that MRI may be more accurate than CT in demonstrating metastatic disease. Although enhanced CT is used in most centres for screening for liver deposits, CT-AP (CT with arterial portography), which requires contrast injection via the superior mesenteric artery, is considered by many to be the most accurate technique for staging liver metastases if surgical resection is being considered. However, thin-section multislice CT with arterial and portal venous phase scanning is likely to replace this. Preoperative identification of the segment of the liver involved can be determined by translation of the segmental surgical anatomy, as defined by Couinaud, to the cross-sectional CT images (Figure 13.43).

The technique of PET/CT is becoming a powerful tool in oncological imaging. This functional and anatomical imaging technique reflects tumour metabolism and allows the detection of otherwise occult metastases. The most common indications for PET/CT have been staging of lymphoma, lung cancer, particularly non-small cell lung cancer, and preoperative assessment of potentially resectable liver metastases such as colorectal carcinoma metastases.

Intraoperative ultrasound is an additional method of staging that provides superb high-resolution imaging of subcentimetre liver nodules that may not be palpable at surgery. This is often used immediately prior to resection of liver metastases.

CHAPTER
14Gastrointestinal
endoscopy

LEARNING OBJECTIVES

To gain an understanding of:

- The role of endoscopy as a diagnostic and therapeutic tool
- The basic organisation of an endoscopy unit and its equipment
- Consent and safe sedation
- Special situations: the key points in managing endoscopy in high-risk patients
- The indications for diagnostic and therapeutic endoscopic procedures including endoscopic ultrasound
- The recognition and management of complications
- Novel techniques for endoscopy of the small bowel
- Advances in diagnostic ability

INTRODUCTION

The gastrointestinal tract has a myriad of functions, such as digestion, absorption and excretion, as well as the synthesis of an array of hormones, growth factors and cytokines. In addition, a complex enteric nervous system has evolved to control its function and communicate with the central and peripheral nervous systems. Finally, as the gastrointestinal tract contains the largest sources of foreign antigens to which the body is exposed, it houses well-developed arms of both the innate and acquired immune system. Therefore, it is not surprising that malfunction or infection of this complex organ results in a wide spectrum of pathology. However, its importance in disease pathogenesis is matched only by its inaccessibility to traditional examination.

Few discoveries in medicine have contributed more to the practice of gastroenterology than the development of diagnostic and therapeutic endoscopy. Although spectacular advances in radiology have occurred recently with the introduction of multislice spiral computed tomography (CT) and magnetic resonance imaging (MRI), the ability to take targeted mucosal biopsies remains a unique strength of endoscopy. Historically, radiological techniques were required to image areas of jejunum and ileum inaccessible to the standard endoscope; however, the introduction of both capsule endoscopy and single/double-balloon enteroscopy allows both diagnostic and therapeutic access to the entire gastrointestinal tract. Image enhancement with techniques such as chromoendoscopy, magnification endoscopy and narrow band imaging allow increased resolution at the mucosal level and increase diagnostic yield. Endoscopic ultrasound can examine all layers of the intestinal wall as well as extraintestinal structures. Finally, experimental techniques such as confocal laser endomicroscopy give resolution at a level compatible with standard histology. The advances in the diagnostic accuracy of endoscopy lend themselves to disease surveillance

for specific patient groups as well as population screening for gastrointestinal malignancy. Likewise, there has been a rapid expansion in the therapeutic capability of endoscopy with both luminal and extraintestinal surgery being performed via endoscopic access.

As in all areas of interventional practice, competent endoscopists must match a thorough grounding in anatomy and physiology with a clear understanding of the capabilities and limitations of the rapidly advancing techniques available. Perhaps most importantly they must appreciate all aspects of patient care including pre-procedural management, communication before and during the procedure and the management of endoscopic complications. This chapter aims to guide the reader through these areas in addition to providing an introduction to the breadth of procedures that are currently performed.

HISTORY OF ENDOSCOPY

Over the last 50 years, endoscopy has become a most powerful diagnostic and therapeutic tool. However, its development required two obvious but formidable barriers to be overcome. First, the gastrointestinal tract is rather long and tortuous and, second, no natural light shines through the available orifices! Therefore, successful visualisation of anything beyond the distal extremities requires a flexible instrument with an intrinsic light source that can transmit images to the operator. The illumination issue was solved in 1879 by Thomas Edison, but 25 years

Thomas Alva Edison, 1847–1931, American physicist and inventor of Menlo Park, NJ, USA, produced the first carbon filament electric light bulb in 1879. His major innovation was the first industrial research laboratory called Menlo Park (1876–1881) and therefore he was called 'The Genius of Menlo Park'. He held the world record of 1093 patents for invention. He was such a poor student that a schoolmaster called him 'addled'. At this, his mother was so furious that she took him out of school and taught him at home.

elapsed before a light source was incorporated into the primitive rigid endoscopes available at that time. The first approach to gastrointestinal tortuosity was an instrument with articulated lenses and prisms, proposed by Hoffmann in 1911. Again, approximately two decades elapsed before this concept was incorporated into a semiflexible gastroscope by Wolf, a fabricator of medical instruments, and Schindler, a physician.

The real breakthrough was the discovery that images could be transmitted using flexible quartz fibres. Although this was first described in the late 1920s, it was not until 1954 that Hopkins built a model of a flexible fibre imaging device. The availability of highly transparent optical quality glass led to the development in 1958 of the first flexible fibreoptic gastroscope by Larry Curtiss, a graduate student in physics, and Basil Hirschowitz, a trainee in gastroenterology. Over the next 30 years, the fibrescope evolved to allow examination of the upper gastrointestinal tract, the biliary system and the colon. In parallel with advances in diagnostic ability, a range of therapeutic procedures was developed (Table 14.1). Although the fibreoptic endoscope has been the workhorse of many endoscopy units over the last three decades, its obsolescence was guaranteed by the invention of the charge coupled device (CCD) in the 1960s, which allowed the creation of a digital electronic image, permitting endoscopic images to be processed by a computer and transmitted to television screens. Thus the modern endoscope was born (Figure 14.1).

History does not sit still, and endoscopic evolution will continue with the replacement of much diagnostic endoscopy with capsule endoscopy and virtual imaging. Enhanced resolution using chromoendoscopy, and even histological grade images, have increased the diagnostic yield of surveillance procedures. Endoscopic ultrasound allows diagnosis and therapy to extend beyond the mucosal surface of the intestine. Traditional endoscopy will therefore become increasingly therapeutic and historical divisions between medicine, radiology and surgery will become progressively blurred. As the complexity of the procedures increases, the distinction between specialist and general endoscopists will become more definite. This reinforces the need for all endoscopic practitioners to have a detailed understanding of the units in which they work and the instruments that they use.

THE MODERN ENDOSCOPY UNIT

Organisation

A well-designed endoscopy unit staffed by trained endoscopy nurses and dedicated administrative staff is essential to support good endoscopic practice and training. Clinical governance with regular appraisal and assessment of performance should be a routine process embedded within the unit philosophy. Endoscopist training demands particular attention, with a transparent process of skills- and theory-based education centred on practical experience and dedicated training courses. Experienced supervision of all trainee endoscopists is essential until competency has been obtained and assessed by an appropriately validated technique such as direct observation of practical skills (DOPS) and review of procedure logbooks. However, all endoscopists should keep an ongoing log to record diagnostic and therapeutic procedure numbers and markers of competency such as colonoscopy completion rates, polyp detection rates, mean sedation use and complication rates. Central to this is an efficient data management system that provides outcome analysis for all aspects of endoscopy including adherence to guidelines, near misses, patient satisfaction, decontamination processes and scope tracking, as well as the more obvious completion and complication rates.

Equipment

A full description of all available endoscopic equipment is beyond the scope of this chapter. However, each unit should have a sufficient range of endoscopes, processors and accessories as dictated by the local case mix and sufficient endoscope numbers to ensure smooth service provision. These should include both forward- and lateral-viewing gastroscopes, an enteroscope for proximal small bowel visualisation and a range of adult and paediatric colonoscopes to aid examination of both redundant and fixed colons. Dedicated small bowel centres require capsule endoscopy and a single/double-balloon enteroscope for ileojejunum visualisation and therapeutics. Larger centres will require linear and radial endoscopic ultrasound, particularly if they specialise in gastrointestinal and hepatobiliary malignancy. An electrosurgical unit is the cornerstone of many therapeutic procedures and this may be supplemented by an argon plasma

coagulation unit and laser units for advanced therapeutics in specialised centres.

Instrument decontamination

Endoscopes will not withstand steam-based autoclaving and therefore require high-level disinfection between cases to prevent transmission of infection. Although accessories may be autoclaved, best practice requires the use of disposable single use items whenever possible. All equipment should be decontaminated to an identical standard whether for use on immunocompromised/infected patients or not. This process involves two equally important stages: first, removal of physical debris from the internal and external surfaces of the instrument and, second, chemical neutralisation of all microbiological agents. A variety of agents are available and endoscopists should familiarise themselves with the agent in use in their department. The British Society of Gastroenterology has developed guidelines for decontamination of endoscopes (www.bsg.org.uk/images/stories/docs/clinical/guidelines/endoscopy/decontamination_2008.pdf). Key points in endoscope decontamination are shown in Summary box 14.1.

Summary box 14.1

Disinfection of endoscopes

- All channels must be brushed and irrigated throughout the disinfection process
- All instruments and accessories should be traceable to each use, patient and cleaning cycle
- All staff should be trained and protected (particularly if glutaraldehyde is used in view of its immune-sensitising properties)
- Regular monitoring of disinfectant power and microbiological contamination should be performed

There are currently no reliable means of decontaminating scopes from contact with prion-associated conditions such as new variant Creutzfeldt–Jakob disease (nvCJD). Endoscopy should be avoided in patients thought to be at risk of this condition, as instruments may require quarantine until the diagnosis can be excluded (which is often only possible post-mortem). In many countries, previously exposed endoscopes are available if a patient with suspected nvCJD requires endoscopy. Sheathed biopsy forceps are now being developed to allow samples to be taken from high-risk individuals without compromising the endoscope.

CONSENT IN ENDOSCOPY

Approximately 1 per cent of medical negligence claims in the USA relate to the practice of endoscopy. Many of these could have been avoided by a careful explanation of the procedure, including an honest discussion of the risks and benefits. Therefore, obtaining informed consent is a cornerstone of good endoscopic practice. It preserves a patient's autonomy, facilitates communication and acts as a shield against future complaints and claims of malpractice.

The most important aspect of the consent procedure is that a patient understands the nature, purpose and risk of a particular procedure. Current guidelines would suggest that a

patient should be informed of minor adverse events with a risk of more than 10 per cent and serious events with an incidence of more than 0.5 per cent. The key risks of endoscopy are summarised in Summary box 14.2. The 2008 British Society of Gastroenterology guidelines for consent can be found using the link www.bsg.org.uk/images/stories/docs/clinical/guidelines/endoscopy/consent08.pdf

Summary box 14.2

The risks of endoscopy

- Sedation related cardiorespiratory complications
- Damage to dentition
- Aspiration
- Perforation or haemorrhage after endoscopic dilatation/therapeutic endoscopic ultrasound
- Perforation, infection and aspiration after percutaneous endoscopic gastrostomy insertion
- Perforation or haemorrhage after flexible sigmoidoscopy/colonoscopy with polypectomy
- Pancreatitis, cholangitis, perforation or bleeding after endoscopic retrograde cholangiopancreatography

SAFE SEDATION

If performed competently, the majority of diagnostic endoscopy and colonoscopy can be performed without sedation or with pharyngeal anaesthesia alone. However, therapeutic procedures may cause pain and patients are often anxious; thus in most countries sedation and analgesia are offered to achieve a state of conscious sedation (**not** anaesthesia). Medication-induced respiratory depression in elderly patients or those with comorbidities is the greatest cause of endoscopy-related mortality and, therefore, safe sedation practices are essential. The involvement of anaesthetists to advise on appropriate protocols is recommended (Summary box 14.3). Endoscopy in certain situations (particularly paediatric endoscopy) requires general anaesthetic – this should only be undertaken by appropriately trained staff with adequate equipment available.

ENDOSCOPY IN DIABETIC PATIENTS

As approximately 2 per cent of the population is diabetic, managing glycaemic control before and after endoscopy is an essential aspect of endoscopic practice. Factors influencing management include the type of diabetes, the procedure that is planned, the preparation/recovery time, and the history of diabetic control in the individual patient. Thus, a poorly controlled insulin-dependent diabetic undergoing colonoscopy will require more input than a type 2 diabetic on oral hypoglycaemic medication undergoing upper gastrointestinal endoscopy. All patients should bring their own medication to the unit and should be advised not to drive in case there is an alteration in their glycaemic control. The majority of patients can be managed using clear protocols on an outpatient basis; however, elderly patients and those with brittle control should be admitted. In general, diabetic patients should be endoscoped first on the morning list. In complex cases the diabetic team should be involved.

Summary box 14.3**Sedation in endoscopy**

- Pharyngeal anaesthesia may increase the risk of aspiration in sedated patients
- Comorbidities must be identified so that sedation can be individualised
- All sedated patients require secure intravenous access
- Benzodiazepines reach their maximum effect 15–20 min after administration – doses should be titrated carefully, particularly in the elderly or those with comorbidities
- Co-administration of opiates and benzodiazepines has a synergistic effect – opiates should be given first and doses need to be reduced
- The use of supplementary oxygen is essential in all sedated patients
- Sedated patients require pulse oximetry to monitor oxygen saturation; high-risk patients or those undergoing high-risk procedures also require blood pressure and electrocardiogram monitoring
- A trained assistant should be responsible for patient monitoring throughout the procedure
- Resuscitation equipment and sedation reversal agents must be readily available
- The use of anaesthetic agents such as propofol for complex procedures requires specialist training
- The half-life of benzodiazepines is 4–24 hours – appropriate recovery and monitoring is essential. Post-procedural consultations may not be remembered, and patients must be advised not to drink alcohol or drive for 24 hours

ANTIBIOTIC PROPHYLAXIS

The majority of endoscopy can be performed safely without the need for routine antibiotic prophylaxis. However, given that certain endoscopic procedures are associated with a significant bacteraemia (Table 14.2), there are several specific situations where antibiotic cover is required to prevent either bacterial endocarditis, infection of surgical prostheses or systemic sepsis. In general, the risk of infection relates to the level of bacteraemia and the risk of the underlying medical condition. Traditionally, patients with a previous history of endocarditis or a metallic heart valve received antibiotic prophylaxis for all endoscopic procedures, and many national guidelines still reflect this. However, UK guidelines have recently changed in response to the low reported incidence of infective endocarditis in this patient group undergoing endoscopy (www.bsg.org.uk/images/stories/docs/clinical/guidelines/endoscopy/prophylaxis_09.pdf). Patients with severe neutropenia may also require antibiotic prophylaxis for endoscopy. The antibiotic regime used will depend on local guidelines. Procedures such as endoscopic percutaneous gastrostomy are associated with a significant incidence of infection, particularly if inserted for malignancy. There is excellent evidence that antibiotic prophylaxis reduces this complication and a single intravenous injection of coamoxiclav should be administered before the procedure. Ciprofloxacin is routinely used during endoscopic manipulation of an obstructed biliary tree in which it is unlikely that complete drainage will be achieved or there is significant comorbidity. Finally, patients

Table 14.2 Approximate incidence of bacteraemia in immunocompetent individuals following various procedures involving the gastrointestinal tract.

Procedure	Incidence of bacteraemia (%) ^a
Rectal digital examination	4
Proctoscopy	5
Barium enema	11
Tooth brushing	25
Dental extraction	30–60
Colonoscopy	2–4
Diagnostic upper gastrointestinal endoscopy	4
Sigmoidoscopy	6–9

Oesophageal varices sclerotherapy	10–50 ^b
Oesophageal dilatation/prosthesis	34–54
Oesophageal laser therapy	35
EUS ± fine needle aspirate	0–6

^aSummary of published data.

^bHigher after emergency than after elective management.

ERCP, endoscopic retrograde cholangiopancreatography; EUS, endoscopic ultrasound.

with chronic liver disease and ascites undergoing variceal sclerotherapy should receive antibiotic prophylaxis to prevent bacterial peritonitis.

ANTICOAGULATION IN PATIENTS UNDERGOING ENDOSCOPY

Many patients undergoing endoscopy may be taking medication that interferes with normal haemostasis, such as warfarin, heparin, clopidogrel or aspirin. The key points to remember when managing anticoagulants in patients undergoing endoscopy are given in Summary box 14.4.

Summary box 14.4**Managing anticoagulants in patients undergoing endoscopy**

It is important to recognise and understand:

- The risk of complications related to the underlying gastrointestinal disease from anticoagulant therapy
- The risk of haemorrhage related to an endoscopic procedure in the setting of anticoagulant therapy
- The risk of a thromboembolic/ischaemic event related to interruptions of anticoagulant therapy

Gastrointestinal bleeding in the anticoagulated patient

The risk of clinically significant gastrointestinal bleeding in patients on warfarin is increased, particularly in patients with a past history of similar events, if the international normal-

ised ratio (INR) is above the therapeutic range or if they are taking concomitant aspirin/non-steroidal anti-inflammatory drugs (NSAIDs). In these situations the risk of reversing the anticoagulation must be weighed against the risk of ongoing haemorrhage. If complete reversal is not appropriate, correction of the INR to approximately 1.5 is usually sufficient to allow endoscopic diagnosis and therapy. Anticoagulation can be resumed 24 hours after successful endoscopic therapy. If rapid resumption of anticoagulation is required, intravenous heparin should be used.

Elective endoscopy in the anticoagulated patient

Endoscopic procedures vary in their potential to produce significant or uncontrolled bleeding. Diagnostic oesophagogastroduodenoscopy (OGD), colonoscopy, enteroscopy and endoscopic retrograde cholangiopancreatography (ERCP) without sphincterotomy are considered low risk, as is mucosal biopsy. High-risk procedures include colonoscopic polypectomy (1–2.5 per cent), gastric polypectomy (4 per cent), laser ablation of tumour (6 per cent), endoscopic sphincterotomy (2.5–5 per cent) and procedures with the potential to produce bleeding that is inaccessible or uncontrollable by endoscopic means, such as dilatation of benign or malignant strictures, percutaneous gastrostomy insertion and endoscopic ultrasound (EUS)-guided fine-needle aspiration. Likewise, the probability of a thromboembolic complication during temporary cessation of anticoagulant therapy depends on the underlying medical condition (see Table 14.3 and Summary box 14.5).

Table 14.3 The risk of a thromboembolic event varies according to the underlying medical condition.

Condition	Risk
Atrial fibrillation with valvular heart disease	High
Mechanical mitral valve	High
Mechanical valve and previous thromboembolic event	High
Deep vein thrombosis	Low
Uncomplicated atrial fibrillation	Low
Bioprosthetic valve	Low
Mechanical aortic valve	Low

Aspirin, non-steroidal anti-inflammatory drugs and anti-platelet therapies

Aspirin and NSAIDs inhibit platelet cyclo-oxygenase resulting in suppression of thromboxane A2-induced platelet aggregation. Limited published data do not suggest an increased bleeding risk in patients taking standard doses and, therefore, there is no need to discontinue therapy before endoscopic procedures. Increasing evidence suggests an increased risk of bleeding after high-risk endoscopic procedures in patients taking clopidogrel and ticlodipine. However, there is also a high risk of acute myocardial infarction or death if clopidogrel is discontinued early after coronary stent insertion, which may extend to one year post-procedure. Therefore, clopidogrel should not be discontinued in this situation without discussion with a cardiologist. If clopidogrel therapy needs to be discontinued prior to an endoscopic procedure this should be limited to a maximum of 5 days as the risk of stent thrombosis increases after this interval.

Summary box 14.5

Recommendations concerning anticoagulant management

Low-risk procedures

- No adjustment to anticoagulation required
- Check INR 1 week before procedure
- Avoid elective procedures when anticoagulation is above the therapeutic range

High-risk procedure in a patient with a low-risk condition

- Discontinue warfarin 5 days before the procedure
- Check INR on day of procedure to ensure <1.5
- Restart warfarin 24 hours after procedure if uncomplicated and recheck INR in one week

High-risk procedure in a patient with a high-risk condition

- Discontinue warfarin 5 days before the procedure
- Start low molecular weight heparin 2 days after stopping warfarin
- Check INR on day of procedure to ensure <1.5
- Omit LMWH on day of procedure
- Warfarin may be resumed the night of the procedure
- LMWH should be continued until INR adequate
- The decision to administer intravenous heparin should be individualised

UPPER GASTROINTESTINAL ENDOSCOPY

OGD is the most commonly performed endoscopic procedure. Excellent visualisation of the oesophagus, gastro-oesophageal junction, stomach, duodenal bulb and second part of the duodenum can be obtained (Figure 14.2). Retroversion of the gastroscope in the stomach is essential to obtain complete views of the gastric cardia and fundus (Figure 14.2). Traditional forward-viewing endoscopes do not adequately visualise the ampulla, and a side-viewing scope should be used if this is essential. Likewise, although it is possible to reach the third part of the duodenum with a standard 120-cm instrument, a longer enteroscope is required if views beyond the ligament of Treitz are required. In addition to clear mucosal views, diagnostic endoscopy allows mucosal biopsies to be taken, which may either undergo processing for histological examination or be used for near-patient detection of *Helicobacter pylori* infection using a commercial urease-based kit. In addition, brushings may be taken for cytology and aspirates for microbiological culture.

Indications for oesophagogastroduodenoscopy

A full assessment of the role of OGD is outside the scope of this chapter. It will vary with local circumstances and the availability of alternative diagnostic techniques. OGD is usually appropriate when a patient's symptoms are persistent despite appropriate empirical therapy or are associated with warning signs such as intractable vomiting, anaemia, weight loss, dysphagia or bleeding. It is also part of the diagnostic work-up for patients with anaemia, symptoms of malabsorption and chronic diarrhoea. However, increasing ease of access to OGD with the availability of 'open access' endoscopy has resulted in a significant number of unnecessary procedures being performed in young patients with

Wenzel Treitz, 1819–1872, Professor of Pathology, Prague, The Czech Republic.

Figure 14.2 A normal upper gastrointestinal endoscopy showing the gastro-oesophageal junction (a), the gastric fundus in the 'J' position (b), the gastric antrum (c) and the second part of the duodenum (d).

dyspepsia or gastro-oesophageal reflux disease (GORD). This has led to a number of international gastroenterology societies proposing guidelines for the management of dyspepsia/GORD, including the empirical use of acid suppression and non-invasive *H. pylori* tests, such as urease breath tests and serology (e.g. the National Institute for Health and Clinical Excellence guidelines on dyspepsia: www.nice.org.uk/CG017NICEguideline). In addition to the role of OGD in diagnosis, it is also commonly used in the surveillance of neoplasia development in high-risk patient groups. Whereas there is consensus about its role in genetic conditions such as familial adenomatous polyposis and Peutz–Jeghers syndrome, controversy remains about the role and frequency of endoscopic surveillance in premalignant conditions such as Barrett's oesophagus and gastric intestinal metaplasia.

Therapeutic oesophagogastrroduodenoscopy

Increasing technological advances have revolutionised the therapeutic applications of upper gastrointestinal endoscopy. However, appropriate patient selection and monitoring is essential to minimise complications. The most common therapeutic endoscopic procedure performed as an emergency is the control of upper gastrointestinal haemorrhage of any aetiology. Band ligation has replaced sclerotherapy in the management of oesophageal varices (Figure 14.3), whereas sclerotherapy using thrombin-based glues can be used to control blood loss from

gastric varices. Injection sclerotherapy with adrenaline coupled with a second haemostatic technique, such as heater probe vessel obliteration or haemoclip application, remains the technique of choice for a peptic ulcer with an active arterial spurt or stigmata of recent haemorrhage (Figure 14.4). This should be followed by 72 hours of intravenous proton pump inhibition in all cases. Chronic blood loss from angiodysplasia is most safely treated with argon plasma coagulation because of the controlled depth of burn compared with alternative thermal techniques (Figure 14.5).

Benign oesophageal and pyloric strictures may be dilated under direct vision with 'through the scope' (TTS) balloon dilators or the more traditional guidewire-based systems such as Savary–Guillard bougie dilators (Figure 14.6). Intractable disease can be treated by the insertion of a removable stent. Likewise, the lower oesophageal sphincter hypertension associated with achalasia can be reduced by pneumatic balloon dilatation, although the procedure may need to be repeated every few years and the large (2–3 cm) balloons required are associated with a significantly increased risk of perforation. An alternative is the injection of botulinum toxin, which has a considerably more favourable side-effect profile but a shorter duration of benefit.

There are an increasing number of endoscopic techniques available to reduce gastro-oesophageal reflux that rely on tightening the loose gastro-oesophageal junction by plication, the

John Law Augustine Peutz, 1886–1968, Chief Specialist for Internal Medicine, St. John's Hospital, The Hague, The Netherlands.

Norman Rupert Barrett, 1903–1979, surgeon, St. Thomas's Hospital, London, UK.

Figure 14.3 Grade 2 oesophageal varices (a), which can be treated by the application of bands to ligate the vessel and reduce blood flow (b).

application of radial thermal energy or injection of a bulking agent. Although many of these techniques deliver short-term clinical benefits and a reduction in 24-hour oesophageal acid exposure, none has demonstrated long-term benefits in a group of patients resistant to proton pump inhibitors. Likewise, endoscopic techniques to tackle obesity, such as gastric balloon insertion, have not been associated with evidence of long-lasting benefit. In contrast, there is clear evidence that the insertion of a percutaneous endoscopic gastrostomy (PEG) tube enhances

nutritional and functional outcome in patients unable to maintain oral nutritional intake (Figure 14.7). PEG insertion is often a prelude to treatment of complex orofacial malignancy, and may be used to support nutrition in patients with alternative malignant, degenerative or inflammatory diseases.

The deployment of 'memory metal' self-expanding stents with or without a covering sheath inserted over a stiff guidewire leads to a significant improvement in symptomatic dysphagia and quality of life in patients with malignant oesophageal and

Figure 14.4 A gastric ulcer with active bleeding (a) is initially treated with adrenaline injection to achieve haemostasis (b). Two haemoclips are then applied to prevent re-bleeding (c and d).

Figure 14.5 The classic appearance of gastric antral vascular ectasia (GAVE), which is often treated with argon plasma coagulation.

gastric outlet obstruction (Figure 14.8). Covered stents are the mainstay of treatment for benign or malignant tracheo-oesophageal fistulae. However, the area of greatest progress over the last few years has been in the endoscopic management of early oesophageal and gastric neoplasia with endoscopic mucosal resection (EMR) and the destruction of areas of high-grade dysplasia (HGD) using either EMR (Figure 14.9) or photodynamic therapy. However, long-term follow-up studies are required to ensure that the endoscopic ablation of areas of HGD has an impact on the progression to cancer.

Figure 14.6 A pyloric stricture (a) can be dilated using a 'through the scope' balloon under direct vision to minimise complications (b).

Complications of diagnostic and therapeutic oesophagogastroduodenoscopy

Diagnostic upper gastrointestinal endoscopy is a safe procedure with minimal morbidity as long as appropriate patient selection and safe sedation practices are embedded in the unit policy. The mortality rate is estimated to be less than 1:10000, with a complication rate of approximately 1:1000. As mentioned above, the majority of adverse events relate to sedation and patient comorbidity. Particular caution should be exercised in patients with recent unstable cardiac ischaemia and respiratory compromise. Perforation can occur at any point in the upper gastrointestinal tract, including the oropharynx. It is rare during diagnostic procedures and is often associated with inexperience. Perforation is more common in therapeutic endoscopy, particularly oesophageal dilatation and EMR for early malignancy. Early diagnosis significantly improves outcome and thus all staff must be alert to the symptoms (Summary box 14.6).

Summary box 14.6

Symptoms of endoscopic oesophageal perforation

- Neck/chest pain
- Dysphagia/drooling saliva
- Abdominal pain
- Increasing tachycardia
- Hypotension
- Surgical emphysema

Prompt management includes radiological assessment using CT/water-soluble contrast studies, strict nil by mouth, intravenous fluids and antibiotics, and early review by an experienced upper gastrointestinal surgeon.

ENDOSCOPIC ASSESSMENT OF THE SMALL BOWEL

Introduction and indications

The requirement to visualise, biopsy and treat the small bowel is far less than in the stomach, biliary tree or colon, resulting in a time lag in technological advances. The most frequent indication is the investigation of gastrointestinal blood loss, which may present with either recurrent iron deficiency anaemia (occult haemorrhage) or recurrent overt blood loss per rectum (cryptic haemorrhage) in a patient with normal OGD (with duodenal biopsies) and colonoscopy. Other indications include the investigation of malabsorption; the exclusion of cryptic small bowel inflammation such as Crohn's disease in patients with diarrhoea/abdominal pain and evidence of an inflammatory response; targeting lesions seen on radiological investigations; and surveillance for neoplasia in patients with inherited polyposis syndromes.

A standard enteroscope is able to reach and biopsy lesions detected in the proximal small bowel; however, even in the most experienced hands this is limited to approximately 100 cm distal to the pylorus, although the use of a stiffening overtube

Figure 14.7 A schematic diagram of percutaneous endoscopic gastrostomy insertion. A standard endoscopy is performed to ensure that there are no contraindications to gastrostomy insertion. The stomach is insufflated with air and a direct percutaneous needle puncture made at a point where the stomach abuts the abdominal wall. Lignocaine is infused on withdrawal (a). A trochar is inserted and a wire passed into the stomach, which can be caught with a snare (b). The scope is withdrawn, pulling the wire out through the mouth, at which point it is attached to the gastrostomy tube (c). The gastrostomy is pulled through into the stomach and out through the track created by the trochar insertion (d).

may increase this somewhat. The procedure takes approximately 45 minutes and may be uncomfortable, requiring high doses of sedation with the attendant increased risk of perforation and sedation-related morbidity. Sonde endoscopy, in theory, has the potential to examine the entire small bowel. In this procedure a long thin endoscope is inserted transnasally into the stomach and pushed through the pylorus with a gastroscope passed through the mouth. It is carried distally by peristalsis, which propels a balloon inflated at the tip. The technique has several limitations including a long examination time (6–8 hours), patient discomfort, the danger of perforation and the inability to perform therapeutic procedures. For these reasons it is not widely performed and will soon become obsolete.

Therefore, until recently, barium follow-through or enteroclysis were the most effective imaging modalities to visualise the distal duodenum, jejunum and ileum. Obviously these techniques do not give true mucosal views, and outside specialist centres their decreasing use has led to diminished expertise and a reduced diagnostic yield. There have been rapid advances in axial radiological techniques such as MRI and CT enteroclysis, which demonstrate excellent diagnostic accuracy in this area

Figure 14.8 A self-expanding metal stent may be used to alleviate symptoms relating to malignant oesophageal strictures.

Figure 14.9 Novel upper gastrointestinal therapeutic uses of oesophagogastroduodenoscopy include the use of endoscopic mucosal resection to remove early gastric cancer leaving a clean base.

(see Chapter 13). However, although these techniques may yield information about vascularity and bowel wall thickening, they do not allow direct mucosal views, have no biopsy capability and have limited scope in terms of therapeutics. Until recently, if an area of interest was outside the reach of a standard enteroscope, direct access via enterotomy under either laparoscopic or open surgery was required. Two major clinical advances over the last 2–3 years have revolutionised small bowel diagnosis and therapeutics. First, the development of the capsule endoscope allows diagnostic mucosal views of the entire small bowel to be obtained with minimal discomfort in unsedated patients. Second, the novel technique of single/double-balloon enteroscopy allows endoscopic access to the entire small bowel for biopsy and therapeutics (Table 14.4).

Capsule endoscopy

The prototype capsule endoscope was developed at the Royal London Hospital in the UK by Professor Paul Swain. Several companies have developed different systems for routine clinical use, but the basic principles remain identical. The technique requires three main components: an ingestible capsule, a portable data recorder and a workstation equipped with image-processing software. The capsule consists of an optical dome and lens, two light-emitting diodes, a processor, a battery, a transmitter and an antenna encased in a resistant coat the size of a large vitamin pill (Figure 14.10). It acquires video images during natural propulsion through the digestive system that it transmits via a digital radio-frequency communication channel to the recorder unit worn outside the body; this also contains sensors which allow basic localisation of the site of image capture within the abdomen. Upon completion of the examination, the physician transfers the accumulated data to the workstation for interpretation via a high-capacity digital link. The workstation is a modified personal computer required for off-line data storage, interpretation and analysis of the acquired images, and report generation.

The small bowel capsule provides good visualisation from mouth to colon with a high diagnostic yield. It compares favourably with the 'gold standard' techniques for the localisation of cryptic and occult gastrointestinal bleeding and the diagnosis of small bowel Crohn's disease. Use of the capsule endoscope is contraindicated in patients with known small bowel strictures in which it may impact, resulting in acute obstruction requiring retrieval at laparotomy or via laparoscopy. Severe gastroparesis and pseudo-obstruction are also relative contraindications to its use. Some units advocate a barium follow-through to exclude stricturing disease in all patients before capsule endoscopy. An alternative is to use a 'dummy' patency capsule that can be tracked via a hand-held device or conventional radiology as it passes through the intestine; it dissolves after 40 hours if it becomes impacted. Technology in this field is rapidly advancing with capsule systems designed to image the oesophagus and colon nearing the market. Prototype capsules that can be directed, take biopsies and deliver thermal therapy to angioectasia are in development.

Table 14.4 Comparison of the advantages and disadvantages of the currently available modalities to endoscope the small intestine.

Technique	Advantages	Disadvantages
Traditional enteroscopy	Simple technique with wide availability Full range of therapeutics available Performed under sedation	Some discomfort Can only access proximal small bowel
Capsule endoscopy	Able to visualise the entire small bowel Preferable for patients No sedation Painless	No biopsies Not controllable and no accurate localisation Variable transit Incomplete studies due to battery life Not suitable for patients with strictures Large capsule to swallow
Double/single-balloon enteroscopy	Able to visualise the entire small bowel Full range of therapeutics	Requires sedation/general anaesthesia Patient discomfort May take 3–4 hours; may require admission Specialist centres only Complications include perforation

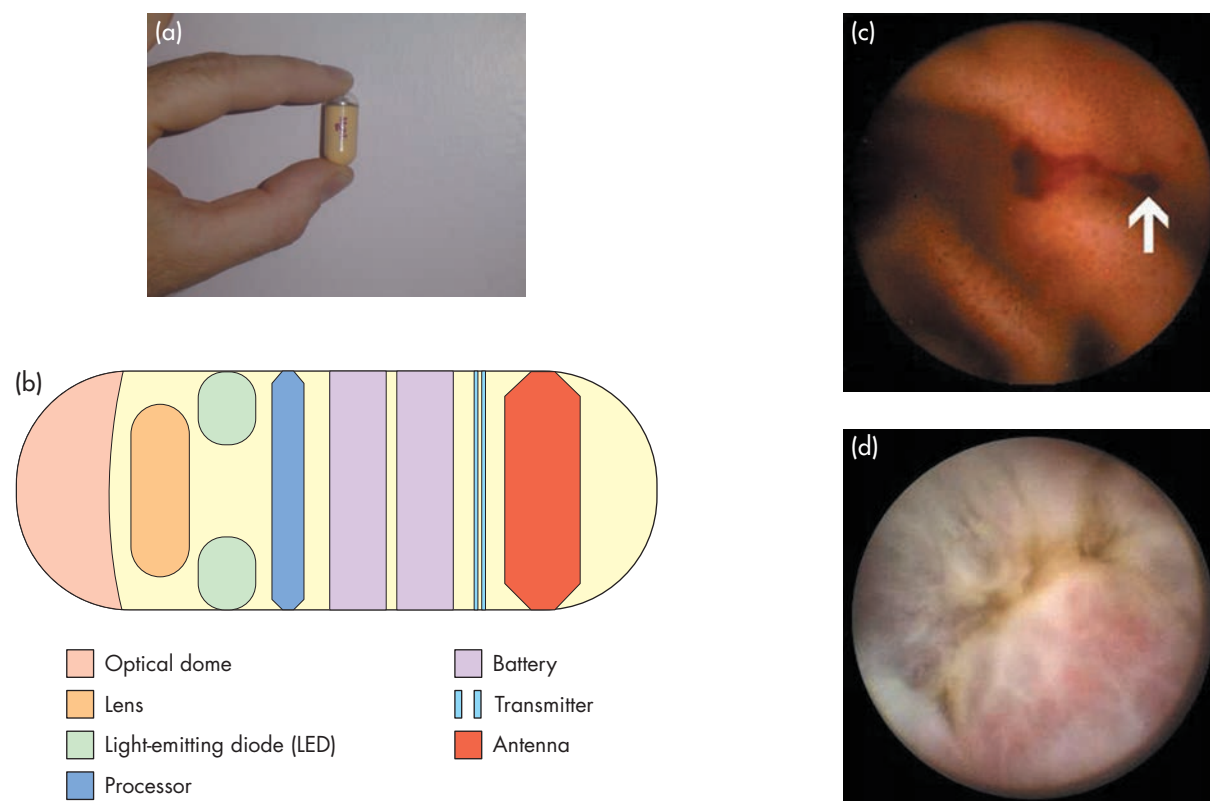

Figure 14.10 Complete diagnostic visualisation of the small bowel can be achieved with capsule endoscopy (a). The structure of the capsule is shown in (b). Clear mucosal pictures can be achieved here showing angioectasias (arrow) (c) and small bowel Crohn's disease (d).

Single/double-balloon enteroscopy

This technique allows the direct visualisation of and therapeutic intervention for the entire small bowel and may be attempted via either the oral or rectal route. Double-balloon enteroscopy was developed in 2001 in Japan; it involves the use of a thin enteroscope and an overtube, which are both fitted with a balloon. The procedure is usually carried out under general anaesthesia, but may be undertaken with the use of conscious sedation. The enteroscope and overtube are inserted through either the mouth or anus and steered to the proximal duodenum/terminal ileum in the conventional manner. Following this the

endoscope is advanced a small distance in front of the overtube and the balloon at the end is inflated. Using the assistance of friction at the interface between the enteroscope and intestinal wall, the small bowel is accorded back to the overtube. The overtube balloon is then deployed and the enteroscope balloon is deflated.

The process is then continued until the entire small bowel is visualised (Figure 14.11). In single-balloon enteroscopy, developed more recently, an enteroscope and overtube are used, but only the overtube has a balloon attached. A full range of therapeutics including diagnostic biopsy, polypectomy, argon

Figure 14.11 The technique of double-balloon enteroscopy is performed with an adapted enteroscope and overtube, both of which have inflatable balloons at their tip.

plasma coagulation and stent insertion are available for balloon enteroscopy. Some experts advocate routine capsule endoscopy before balloon enteroscopy in an attempt to localise any lesions and plan whether oral or rectal access is more appropriate. The indications for single/double-balloon endoscopy are given in Summary box 14.7.

Summary box 14.7

Current established indications for single/double-balloon endoscopy

- Bleeding from the gastrointestinal tract of obscure cause
- Iron deficiency anaemia with normal colonoscopy and gastroscopy
- Visualisation of and therapeutic intervention for abnormalities seen on traditional small bowel imaging/capsule endoscopy

ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY

This procedure involves the use of a side-viewing duodenoscope, which is passed through the pylorus and into the second part of the duodenum to visualise the papilla. This is then cannulated, either directly with a catheter or with the help of a guidewire (Figure 14.12). Occasionally, a small pre-cut is required to gain access. By altering the angle of approach one can selectively cannulate the pancreatic duct or biliary tree, which is then visualised under fluoroscopy after contrast injection. The significant range of complications associated with this procedure and improvements in radiological imaging using magnetic resonance cholangiopancreatography (MRCP) have rendered much diagnostic ERCP obsolete, and thus most procedures are currently performed for therapeutic purposes. There is still a role for accessing cytology/biopsy specimens.

Therapeutic endoscopic retrograde cholangiopancreatography

It is essential to ensure that patients have appropriate assessment prior to therapeutic ERCP, which is associated with a significant morbidity and occasional mortality. All patients require routine blood screening including a clotting screen. Assessment of res-

piratory and cardiovascular comorbidity is essential. Patients with an obstructed biliary system require antibiotic prophylaxis. The use of supplementary oxygen and both cardiac and oxygen saturation monitoring during the procedure are essential because of the high levels of sedation that are often required. The most common indication for therapeutic ERCP is the relief of biliary obstruction due to gallstone disease and benign or malignant biliary strictures. The pre-procedural diagnosis can be confirmed by contrast injection, which will clearly differentiate the filling defects associated with gallstones and the luminal narrowing of a stricture. If there is likely to be a delay in relieving an obstructed system, percutaneous drainage may be required.

The cornerstone of gallstone retrieval is an adequate biliary sphincterotomy, which is normally performed over a well-positioned guidewire using a sphincterotome connected to an electrosurgical unit. Most gallstones less than 1 cm in diameter will pass spontaneously in the days and weeks following a sphincterotomy, but most endoscopists prefer to ensure duct clearance at the initial procedure to reduce the risk of impaction, cholangitis or pancreatitis. This can be achieved by trawling the duct using a balloon catheter or by extraction using a wire basket. If standard techniques fail, large or awkwardly placed stones can be crushed using mechanical lithotripsy. If adequate stone extraction cannot be achieved at the initial ERCP it is imperative to ensure biliary drainage with the placement of a removable plastic stent while alternative options are considered. These include surgery, endoscopically directed shockwaves under direct choledochoscopic vision using a mother and baby scope, and extracorporeal shockwave lithotripsy with subsequent ERCP to remove stone fragments.

Dilation of benign biliary strictures uses balloon catheters similar to those used in angioplasty inserted over a guidewire under fluoroscopic control. It is traditional to insert a temporary plastic stent to maintain drainage as several attempts at dilation may be required. Self-expanding metal stents are most commonly used for the palliation of malignant biliary obstruction and are also normally inserted after a modest sphincterotomy. Correct stent placement can normally be confirmed by a flow of bile after release and by the presence of air in the biliary tree on follow-up plain abdominal radiographs. Stent malfunction, associated with recurrent or persistent biochemical cholestasis, may be due to poor initial stent position, stent migration, blockage with blood clot or debris, or tumour in-growth. A repeat procedure is required to assess the cause, which can usually be remedied by the insertion of a second stent through the original one.

Figure 14.12 During endoscopic retrograde cholangiopancreatography a side-viewing duodenoscope is positioned opposite the papilla, which can then be cannulated using either a catheter or a guidewire (a). Contrast is injected to achieve a cholangiogram (b).

In addition to the standard techniques discussed above, ERCP is also used for pancreatic disease and the assessment of biliary dysmotility (sphincter of Oddi dysfunction) using manometry in specialist centres. Indications include pancreatic stone extraction, the dilatation of pancreatic duct strictures and the transgastric drainage of pancreatic pseudocysts. To minimise the risks of subsequent pancreatitis, pancreatic sphincterotomy is most safely performed after the placement of a temporary pancreatic stent to prevent stasis within the pancreatic duct.

Complications associated with endoscopic retrograde cholangiopancreatography

The same risks associated with other endoscopic procedures also apply to patients undergoing ERCP, but risks may be increased because of the increased patient frailty and high sedation levels required. Complications specific to ERCP include duodenal perforation (1.3 per cent)/haemorrhage (1.4 per cent) after scope insertion or sphincterotomy, pancreatitis (4.3 per cent) and sepsis (3–30 per cent); the mortality rate approaches 1 per cent. It is important to remember that post-sphincterotomy complications may be retroperitoneal and, therefore, CT scanning is essential in patients with pain, tachycardia or hypotension post-procedure. Although normally mild, post-ERCP pancreatitis can be severe with extensive pancreatic necrosis and a significant mortality rate. Many trials have assessed pharmacological strategies to reduce the incidence of pancreatitis, particularly in high-risk patients (Table 14.5). There is some evidence for the use of periprocedural nitroglycerine or rectal NSAIDs after a high-risk procedure.

Table 14.5 Risk factors for post-ERCP pancreatitis.

Definite	Suspected SOD
	Young age
	Normal bilirubin
	Prior ERCP-related pancreatitis
	Difficult cannulation
	Pancreatic duct contrast injection
	Pancreatic sphincterotomy
	Balloon dilatation of biliary sphincter
Possible	Female sex
	Low volume of ERCPs performed
	Absent CBD stone

CBD, common bile duct; ERCP, endoscopic retrograde cholangiopancreatography; SOD, sphincter of Oddi dysfunction.

COLONOSCOPY

Early attempts at colonoscopy were hindered by poor technique and the limitations of the available instruments. The ability to steer an endoscope around the entire colon and into the terminal ileum was made possible by the development of fully flexible colonoscopes with greater than 90° angulation of the tip. Advances in bowel preparation have enhanced mucosal visualisation during the examination. Two key revelations about the practical performance of colonoscopy have allowed skilled operatives to achieve a greater than 95 per cent caecal intubation rate and frequent ileal intubation with minimal discomfort using

Figure 14.13 The caecal pole may not be easy to identify (a) and, therefore, the endoscopist should confirm complete colonoscopy by visualising the appendix orifice (b) or preferably intubating the terminal ileum (c), which demonstrates villi and Peyer's patches.

light sedation. The first is that continued inward pressure of the endoscope results in the formation of loops within the mobile sigmoid and transverse colon, decreasing angulation control at the tip and removing the beneficial effect of shaft torque to aid steering around acute bends. The second is that pulling back the scope regularly with appropriate torque to ensure a straight passage through the sigmoid colon and around the splenic flexure greatly aids the completion of right-sided examination. Targeted abdominal hand pressure to prevent loops in a mobile colon and regular patient position change to enhance mucosal views and remove residual bowel content are also important aids to successful colonoscopy. It is essential that caecal intubation is

confirmed to avoid missing pathology by incorrectly assuming that the caecal pole has been reached. The landmarks may not be clear and, therefore, visualisation of the appendix orifice or preferably terminal ileal intubation is necessary to confirm a complete colonoscopy (Figure 14.13).

Mucosal biopsies may either be targeted to areas of abnormality or random to exclude microscopic colitis in a patient with chronic diarrhoea but a macroscopically normal mucosa. Despite the increasing sophistication of radiological techniques to assess the colon, such as CT colonography, the ability to biopsy areas of abnormality and resect polyps will ensure that colonoscopy remains the most appropriate investigation for the majority of patients (Summary box 14.8). Several countries, including the USA and the UK, have recently introduced colorectal cancer (CRC) screening programmes in the asymptomatic population once they reach a predetermined age. The goal is to increase the number of early-stage CRCs detected and hence decrease mortality, as well as to identify and remove adenomatous polyps and prevent the onset of disease. There is ongoing debate about the relevant benefits of different screening modalities including colonoscopy, CT colonography, flexible sigmoidoscopy and biannual/one-off faecal occult blood testing with colonoscopy only in positive patients. Whichever modality is used, colonoscopy is essential to resect any polyps identified and biopsy unresectable lesions.

Therapeutic colonoscopy

The most common therapeutic procedure performed at colonoscopy is the resection of colonic polyps (Figure 14.14). Retrieved specimens can be assessed for risk factors for neoplastic progression and an appropriate surveillance strategy determined (www.bsg.org.uk/images/stories/docs/clinical/guidelines/endoscopy/ccs_10.pdf). Small polyps up to 5 mm should be removed by cheese-wiring with a 'cold' snare. Hot biopsy is a technique in which the tip of a small pedunculated polyp is grasped between diathermy biopsy forceps and tented away from the bowel wall.

Summary box 14.8

Indications for colonoscopy

- Rectal bleeding with looser or more frequent stools ± abdominal pain related to bowel actions
- Iron deficiency anaemia (after biochemical confirmation ± negative coeliac serology): oesophagogastroduodenoscopy and colonoscopy together
- Right iliac fossa mass if ultrasound is suggestive of colonic origin
- Change in bowel habit associated with fever/elevated inflammatory response
- Chronic diarrhoea (>6 weeks) after sigmoidoscopy/rectal biopsy and negative coeliac serology
- Follow up of colorectal cancer and polyps
- Screening of patients with a family history of colorectal cancer
- Assessment/removal of a lesion seen on radiological examination
- Assessment of ulcerative colitis/Crohn's extent and activity
- Surveillance of inflammatory bowel disease
- Surveillance of acromegaly/ureterosigmoidostomy

A brief burst of monopolar current is used to coagulate the stalk, allowing the polyp to be removed. This is rarely performed in current practice due to an increased risk of immediate and delayed thermal damage to the bowel wall, particularly in the right colon. Larger polyps with a defined stalk can be resected using snare polypectomy with coagulating current either *en bloc* or piecemeal depending on their size (Figure 14.14). Post-polypectomy bleeding can be prevented by the application of haemoclips or an endoloop to the polyp stalk. Sessile polyps extending over several centimetres can be removed by endoscopic mucosal resection, which involves lifting the polyp away

Figure 14.14 Colonoscopy is the most appropriate investigation to detect colonic polyps (a), which can be removed by snare polypectomy during the same procedure leaving a clean polyp base (b).

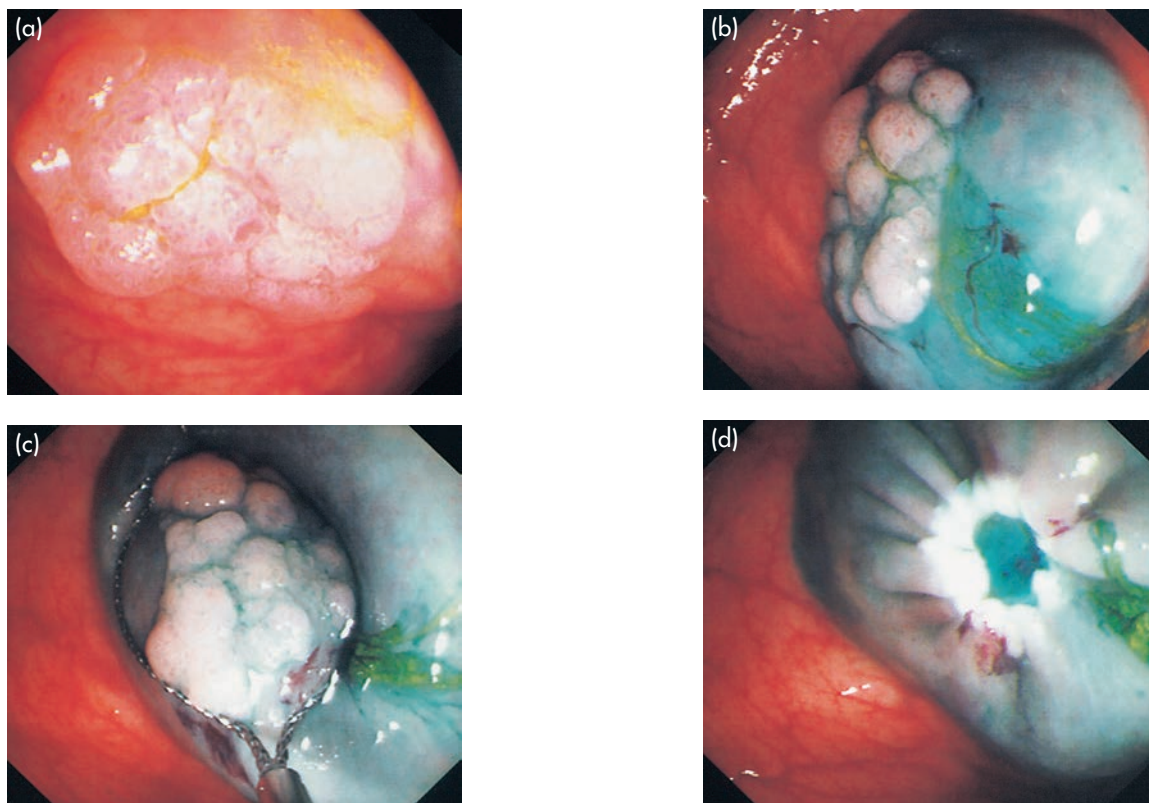

Figure 14.15 Large sessile polyps (a) can be removed by endoscopic mucosal resection. First the polyp is raised on a bed of injected saline containing dye (b). This ensures that there is no submucosal invasion and protects from transmural perforation. A snare is closed around the polyp (c), which is then resected leaving a clean excision base (d).

from the muscularis propria with a submucosal injection of saline to prevent iatrogenic perforation (Figure 14.15). Any residual polyp is obliterated with argon plasma coagulation. Care should be taken with all polypectomies in the right colon where the wall may only be 2–3 mm thick. Removal of large or extensive flat polyps should only be attempted by appropriately trained endoscopists.

Argon plasma coagulation (APC) and alternative thermal therapies such as heater probes are also used in the treatment of symptomatic angioectasias of the colon (Figure 14.16). Laser photocoagulation may be used to debulk colonic tumours not

suitable for resection. As with benign oesophageal strictures, TTS balloons can be used to dilate short (less than 5 cm) colonic strictures. The dilatation of surgical anastomoses gives the most durable benefit as inflammatory strictures tend to recur even if intramucosal steroids are injected at the time of the dilatation.

Figure 14.16 A large angioectasia of the colon. If this results in symptomatic anaemia, it should be obliterated with argon plasma coagulation.

Figure 14.17 Malignant colonic obstruction can be palliated or temporarily relieved by insertion of a self-expanding metal stent.

Finally, the colonoscopic placement of self-expanding metal stents may provide excellent palliation of inoperable malignant strictures (Figure 14.17) and may also play an invaluable role in decompressing an obstructed colon to allow planned as opposed to emergency surgery.

Complications of colonoscopy

Complications during routine diagnostic colonoscopy by an experienced colonoscopist are rare, although perforations have been reported as a result of excessive shaft tip pressure and with excessive air insufflation in severe diverticular disease. Total colonoscopy is contraindicated in the presence of severe colitis; a limited unprepped examination and careful mucosal biopsy only should be performed. Polypectomy is associated with a well-documented rate of perforation (approximately 1 per cent) and haemorrhage (1–2 per cent). Immediate haemorrhage should be managed by re-snaring the polyp stalk where possible and applying tamponade for several minutes followed by careful coagulation if this is unsuccessful. Submucosal adrenaline injection and the deployment of haemoclips are alternatives if this is not possible. Delayed haemorrhage may occur 1–14 days post-polypectomy and can normally be managed by conservative observation. Transfusion may occasionally be required, but repeat colonoscopy is rarely necessary. If recognised at the time of polypectomy, small perforations should be closed using clips and the patient admitted for observation. Symptoms of abdominal pain and cardiovascular compromise after a polypectomy should alert one to the risk of delayed perforation. Patients should be kept nil by mouth and receive intravenous resuscitation and antibiotics. Prompt assessment with plain radiography and a CT scan will often distinguish between a frank perforation and a transmural burn with associated localised peritonitis (the post-polypectomy syndrome). Assessment by an experienced colorectal surgeon is essential, as surgery is often the most appropriate course of action.

ENDOSCOPIC ULTRASOUND

One key disadvantage of conventional endoscopy is that the views are limited to the mucosal surface and it is therefore not possible to diagnose submucosal or extraintestinal pathology.

Figure 14.18 Layers of the intestinal wall.

These limitations can be overcome using endoscopic ultrasound which combines the traditional mucosal image with a separate ultrasound view that clearly depicts the intestinal layers (Figure 14.18) and proximate extraintestinal structures. Its use has revolutionised the staging and management of upper gastrointestinal and hepatobiliary malignancy, as the depth of invasion of a tumour can be accurately assessed at the same time that a biopsy is taken to confirm diagnosis (Figure 14.19). It allows sampling of paraoesophageal and coeliac lymph nodes and drainage of peripancreatic abscess or pseudocysts. The availability of linear and radial probes allows diagnosis and therapy to be appropriately targeted. Its use requires dedicated training and in some centres EUS is performed by an endoscopist working alongside a radiologist. Due to the width and lack of flexibility of the endoultasound scope, as well as the duration of complex therapeutic procedures, sedation is normally required, and some units perform tests using propofol-based anaesthesia. The main indications for endoscopic ultrasound are listed in Table 14.6. All patients undergoing therapeutic endoscopic ultrasound require a normal coagulation screen. Complications include oversedation and oesophageal perforation during diagnostic procedures and haemorrhage/perforation during therapeutic procedures.

Table 14.6 Indications for endoscopic ultrasound.

Diagnostic	Staging of oesophageal/gastric malignancy
	Staging of hepatobiliary malignancy
	Diagnosis of choledoccal microlithiasis
Therapeutic	Biopsy of paraoesophageal lymph nodes
	Biopsy of submucosal upper gastrointestinal lesions
	Biopsy of pancreaticobiliary mass
	Biopsy of portal lymphadenopathy
	Transgastric drainage of pancreatic pseudocyst

FUTURE DIRECTIONS IN ENDOSCOPY

Chromoendoscopy, narrow band imaging and high resolution magnification endoscopy

The ability to enhance lesion detection and achieve near-perfect discrimination of pathology without the need for histology is a common theme of several active areas of endoscopic development. The goal is to allow accurate discrimination of dysplasia grade in areas of Barrett's oesophagus or quiescent ulcerative colitis and to aid polyp detection and the recognition of early gastric and colorectal cancer. The most widely available technique is chromoendoscopy, which involves the topical application of stains or pigments to improve tissue localisation, characterisation or diagnosis. Several agents have been described, which can broadly be categorised as absorptive (vital) stains such as methylene blue, contrast (reactive) stains such as indigo carmine, and those used for tattooing such as India ink. Narrow band imaging (NBI) relies on an optical filter technology that radically improves the visibility of capillaries, veins and other subtle tissue structures by optimising the absorbance and scattering characteristics of light. NBI uses two discrete bands of light: one blue at 415 nm and one green at 540 nm. Narrow band blue light displays superficial capillary networks whereas

Figure 14.19 Endoscopic ultrasound image of an oesophageal tumour invading into the wall.

green light displays sub-epithelial vessels; when combined they offer an extremely high contrast image of the tissue surface. Autofluorescence images can also be used to increase a lesion's discrimination. Finally, high-resolution magnifying endoscopy may be used alone or in combination with one of the above techniques to achieve near-cellular definition of the mucosa (Figure 14.20). New directions for the future include the use of confocal endomicroscopy to achieve histological images at the time of the endoscopic procedure.

CONCLUSIONS

Over the last 30 years endoscopy has become an integral part of the diagnostic work-up of patients with gastrointestinal disease. Whereas advances in radiology may obviate the need for some diagnostic procedures (routine OGD and ERCP), the ability to take mucosal biopsies will ensure that it retains a vital role. Moreover, ongoing advances in technology, such as magnifying endoscopy and chromoendoscopy, are able to give near-histological quality definition to allow near-patient diagnosis. There have also been major advances in the range of conditions that are amenable to endoscopic therapy; such therapy may have substantially lower associated morbidity rates than traditional surgical approaches. However, as the scope of procedures widens and the age range/comorbidities of the patients increases, it is beholden to the endoscopist to ensure that he or she adheres to appropriate governance/consent and sedation practice to minimise complications.

Figure 14.20 Endoscopic diagnostic accuracy can be improved by novel endoscopic techniques. This duodenal adenoma can be seen with conventional white light (a), but its full extent is more clearly delineated using narrow band imaging (b) or chromoendoscopy with indigo carmine (c).

CHAPTER 15

Tissue diagnosis

LEARNING OBJECTIVES

To understand:

- The value and limitations of tissue diagnosis
- How tissue samples are processed
- The role of histology, cytology and the autopsy

To be aware of:

- The role of additional techniques used in clinical practice, including special stains, immunohistochemistry and molecular methods

- The principles of microscopic diagnosis, particularly of neoplasia
- The importance of clinicopathological correlation
- Relevant management issues

INTRODUCTION

For centuries, tissue diagnosis was restricted to macroscopic examination of autopsy material and a limited range of surgical specimens. Microscopic examination of human tissue from autopsies and surgical procedures was introduced in the nineteenth century. Analysis of tissue samples is now an integral part of clinical management. Tissue diagnosis is usually the responsibility of a histopathologist (or 'pathologist'), who is a medically qualified practitioner. The specialty now known as histopathology (or sometimes cellular pathology) encompasses histopathology, cytopathology and autopsy work and is heavily dependent on microscopy.

In the UK, the nature of the histopathologist's work has changed since the 1960s. There has been a steady increase in biopsy numbers, partly because of flexible endoscopy. Many resection specimens are assessed with management and prognosis in mind, the diagnosis having been made preoperatively. Screening programmes have had a major impact. New techniques have improved the quality and value of histopathological assessment, while autopsies have steadily decreased in number. Published minimum standards for the assessment of a specimen,

e.g. a cancer resection, are often in place. In addition, histopathologists are increasingly involved in multidisciplinary patient management meetings.

A modern histopathology department is usually located in a medium-sized or large hospital. Typically, more than 80 per cent of specimens are from the gastrointestinal tract, gynaecological tract or skin. In line with clinical services, highly specialised work, e.g. neuropathology, is confined to major regional centres.

REASONS FOR ASSESSMENT OF TISSUE

There are several reasons for tissue analysis (Summary box 15.1). A new diagnosis may be made, e.g. squamous cell carcinoma, or a known diagnosis confirmed. Microscopic clues may be found, e.g. granulomatous inflammation. Additional expected or unexpected diagnoses may be made. For example, biopsies from a patient with inflammatory bowel disease are taken to confirm the diagnosis and exclude dysplasia but might reveal additional findings, e.g. cytomegalovirus. An appendix removed for appendicitis could contain an incidental carcinoid tumour. Tissue analysis also helps to determine treatment and prognosis. For example, a liver biopsy from a patient with chronic viral hepatitis is not taken to make the diagnosis but instead helps to determine therapy, exclude other diseases (e.g. steatohepatitis) and exclude complications of chronic liver disease (e.g. neoplasia). The pathologist's assessment of resections also helps surgeons to audit their performance.

A tissue sample does not necessarily represent the entire patient. The interpretation of microscopic changes may be considerably enhanced by correlation with the macroscopic findings and the clinical picture. Accordingly, a request form with adequate clinical details should accompany all specimens. Essential details include site of biopsy, date of birth, gender, medications, relevant risk factors and past medical history.

Summary box 15.1

Reasons for tissue analysis

- To make a new diagnosis
- To confirm a suspected or established clinical diagnosis
- To exclude additional diagnoses
- To assist with prognosis
- To help plan management
- Audit

TISSUE SPECIMENS

Routine tissue specimens received by a histopathology department include those intended for histopathological analysis and those for cytopathological assessment (Summary box 15.2). Sometimes these two areas overlap.

Summary box 15.2

Common types of tissue sample

- Histology
 - Formalin-fixed tissue
 - Biopsy
 - Mucosal
 - Punch
 - Needle (core)
 - Currettings
 - Excision
 - Resection
 - Small
 - Large
 - Fresh tissue (usually for frozen section)
- Cytology
 - Cervical
 - Washings, brushings, scrapes
 - Fine-needle aspirate (FNA)
 - Fluids/sputum

Histology

Specimens for histology are arbitrarily classified as biopsies and resections, although the word 'biopsy' can refer to any tissue sample. Types of biopsy include punch biopsy, needle core biopsy and mucosal biopsy. An excision biopsy serves as both a diagnostic biopsy and a small resection. Samples for routine histology are immediately placed in a fixative, usually formalin (10 per cent formaldehyde), to preserve morphology.

Cytology

Cytological specimens can be obtained from many sites using a variety of approaches. Some are easy to obtain, e.g. urine and sputum, whereas others require more intervention.

A conventional cervical smear is obtained by sampling the cervical transformation zone with a brush/broom. Bronchial aspirates, washings and brushings, and gastrointestinal and biliary brushings sample a relatively wide area and may therefore be useful for the diagnosis of neoplasia. Fine-needle aspiration (FNA) cytology may sample accessible sites such as the breast, thyroid and superficial lymph nodes, while FNA from deeper and less accessible structures, e.g. liver, pancreas, kidney and lung, is usually assisted by ultrasound or computed tomography (CT) guidance. Ultrasound-guided transbronchial FNA may be used for mediastinal masses and transmucosal FNA for submucosal gastrointestinal lesions or perivisceral lesions. Fluids may be submitted directly to the laboratory for cytological assessment.

Fresh tissue

The most common indication for submission of a fresh tissue sample (i.e. without fixative) is rapid frozen section diagnosis,

but other indications are microbiological assessment, electron microscopy, chemical analyses (e.g. quantification of iron) and various types of molecular pathological analysis. Before fixing a histology or cytology specimen, the operator should ask whether any of these investigations might be useful.

Risk management

Safety and risk management are priorities in the laboratory. Any risk of contamination by transmissible infection, e.g. hepatitis B virus, HIV, must be minimised by the use of warning labels, especially when fresh tissue is being submitted. Formalin kills many micro-organisms, but any risk of infection should still be notified. Also, formalin itself is toxic to the eyes and skin. Accordingly, leaking or faulty specimen containers should be discarded. Containers must be labelled with the patient's details to avoid errors of identity (Figure 15.1).

Figure 15.1 Sections on glass slides stained with haematoxylin and eosin (H&E). Each slide has a unique specimen identifying number (06S022081), a letter corresponding to the biopsy site (A1–F1) and a site label (e.g. DUOBX for duodenal biopsy).

SPECIMEN PROCESSING

Histology specimen

On arrival in the histopathology department, specimens are given a unique number and submitted for macroscopic assessment and sampling ('cut up'). The largest specimens are opened (e.g. bowel) or sliced (e.g. uterus) and left to fix in formalin for at least 1 day (Figure 15.2a–c). Once fixed and in a suitable condition for cutting, a text description of the specimen and any visible lesion is made. Representative samples ('blocks') are taken from any specimen too large to be processed whole (Figure 15.3). This is usually done by a histopathologist, especially if a case is complex, but sometimes by non-medical staff. A local or national protocol for sampling is often followed. For example, samples from most types of cancer include resection margins, tumour, lymph nodes, non-neoplastic tissue, and any other abnormal areas. Coloured inks may be used to identify resection margins and surfaces (Figure 15.4a and b).

Specimens, or samples from specimens, are placed in plastic cassettes (Figure 15.5), and then embedded in paraffin wax while in the cassette to make a tissue block (Figure 15.6). Sections with a thickness of approximately 5 µm (microns) are cut from the block using a microtome (Figure 15.7). The sections are placed on a glass slide and stained with haematoxylin and eosin (H&E) (Figure 15.1). This work is done by trained staff, known in the UK as biomedical scientists (BMSs). High

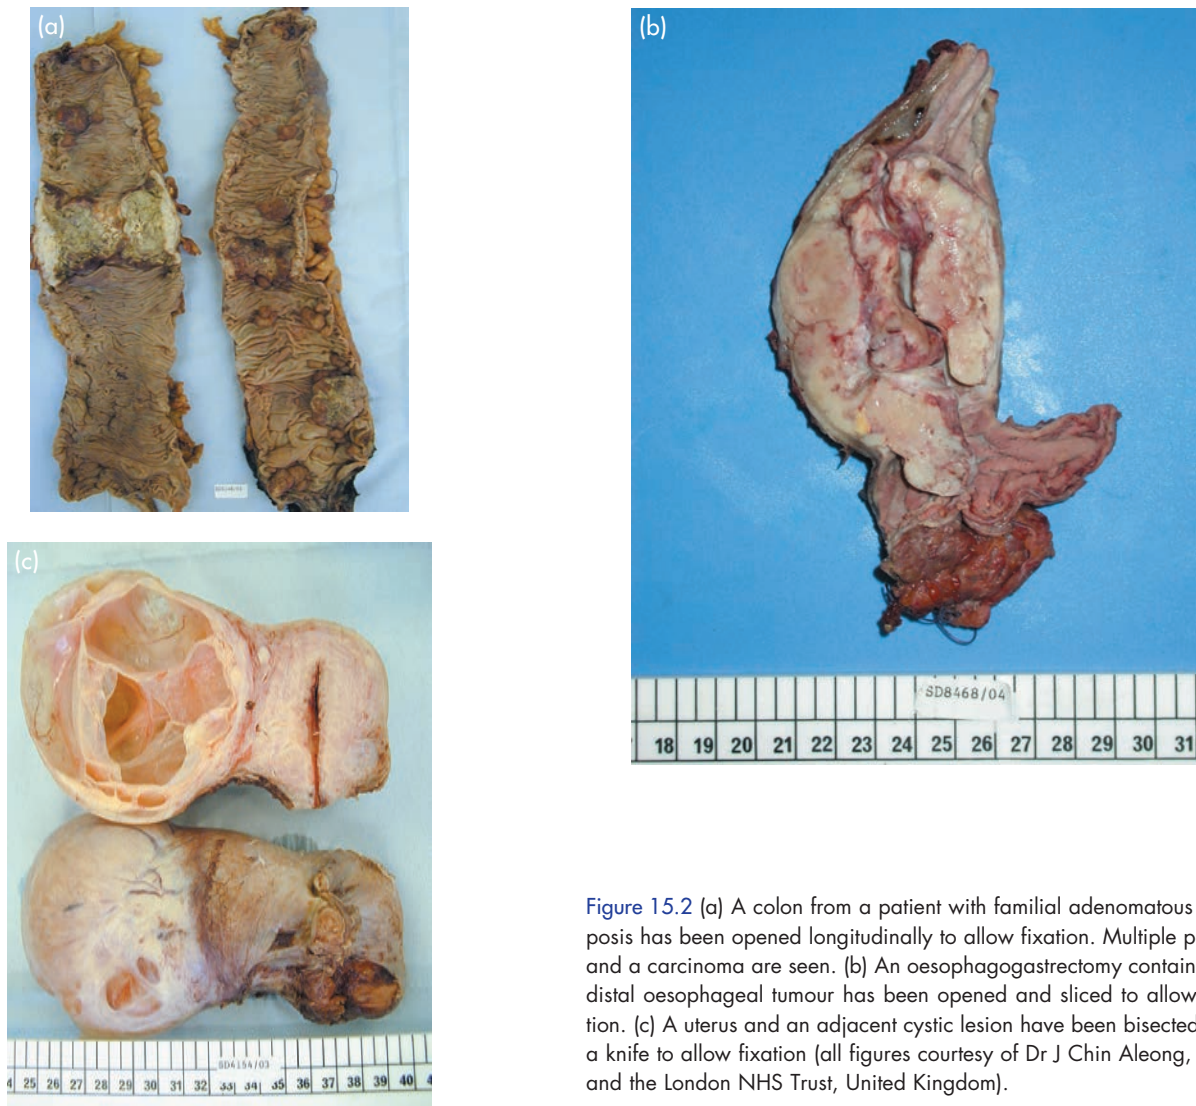

Figure 15.2 (a) A colon from a patient with familial adenomatous polyposis has been opened longitudinally to allow fixation. Multiple polyps and a carcinoma are seen. (b) An oesophagogastric specimen containing a distal oesophageal tumour has been opened and sliced to allow fixation. (c) A uterus and an adjacent cystic lesion have been bisected with a knife to allow fixation (all figures courtesy of Dr J Chin Aleong, Barts and the London NHS Trust, United Kingdom).

standards are necessary because a poorly cut section may have various artefacts, such as lines and folds, which impede accurate assessment. H&E as the first line stain has stood the test of time, probably because it is inexpensive, safe, fast, reliable, familiar and informative.

The stained sections are examined with a microscope (Figure 15.8) by a histopathologist, who correlates the histological features with the clinical details and with the macroscopic description. After any appropriate further studies, the pathologist writes a report which may be entered onto a computer system (Summary box 15.3).

FROZEN SECTION SPECIMEN

Frozen section diagnosis is useful when a rapid answer is necessary. Surgeons are the main users of this service. A fresh tissue sample (i.e. not fixed in formalin) is frozen quickly on a portable metal chuck or similar device, and sections are cut and stained within a few minutes. There are several disadvantages (Summary box 15.4). Fresh tissue carries a higher risk of infection than fixed tissue. The quality of a frozen section slide is inferior to that of routinely processed material, reducing the accuracy and preci-

sion of diagnosis. Small samples are required. In addition, certain types of tissue, e.g. fat, are difficult to process. Furthermore, frozen sections are time-consuming and disruptive for the histopathology department.

Summary box 15.3

Histological processing: sequence of events

- Biopsy or resection specimen received
- Description made
- Specimen sampled (unless small enough to submit in its entirety)
- Specimen or samples placed in cassette(s)
- Paraffin wax block(s) made
- 5-µm sections cut
- Sections put on glass slides
- Sections stained with H&E
- Histopathologist examines slides
- Histology compared with clinical and macroscopic findings
- Further studies if necessary
- Report entered onto computer system
- Report authorised or signed

Figure 15.3 A scalpel is used to take a sample from a resection specimen.

Figure 15.5 A tissue sample from a resection specimen is placed in a cassette.

Figure 15.4 (a) An unopened pancreatoduodenectomy specimen (posterior view). Four inks of different colours have been painted onto various resection margins and external surfaces. (b) Yellow ink on the edge of a histology section (thick arrow). Tumour (thin arrow) lies close to the surface. The distance between the tumour and a surface or a resection margin can be measured (double-headed arrow).

Figure 15.6 Paraffin wax blocks. Cassettes of different colours allow specimens to be organised into groups.

Figure 15.7 A section (thick arrow) being cut from a paraffin wax block (thin arrow) with a microtome.

Summary box 15.4

Frozen section: advantages and disadvantages

Advantages

- Quick diagnosis

Disadvantages

- Labour intensive
- Disruptive
- Risk of infection
- Poorer quality sections
- Small sample required
- Some tissue types difficult to process

Figure 15.8 A double-headed microscope allows a consultant histopathologist and a trainee to view a slide simultaneously.

Cytology specimen

Many samples for cytology can be smeared immediately onto glass slides, fixed (usually in alcohol) or air dried, and stained immediately or later. Several slides are usually produced, some of which are stained with a Papanicolaou (Pap) stain and some with another method such as May–Grünwald–Giemsa (MGG) or Romanowsky. Pap stain is regarded as the preferred stain for fixed specimens while MGG is better for air-dried material. Often the sample will be stained with both. Cervical smears are usually stained with a Pap stain only (Figure 15.9). There has been a move towards liquid-based thin-layer technology for many samples. For liquid-based cytology, the sampling device is usually washed in a liquid medium and the material obtained is then processed in the laboratory using purpose-built equipment.

Figure 15.9 A cervical smear stained with a Papanicolaou stain. Numerous cells are present (courtesy of Professor MT Sheaff, Barts and the London NHS Trust).

George Nicholas Papanicolaou, 1883–1962, Professor of Anatomy, Cornell University, New York, NY, USA, reported on the value of cervical smears in the diagnosis of carcinoma of the uterus in 1941.

Richard May, born 1863, a physician of Munich, Germany.

Gustav Giemsa, 1867–1948, a bacteriologist who became Privatdozent in Chemotherapy, at The University of Hamburg, Hamburg, Germany.

Dimitri Leonidovich Romanovsky, 1861–1921, Professor of Medicine, St. Petersburg, Russia.

Storage

Resection specimens are generally stored for about 4–6 weeks. Tissue blocks are retained for as long as space permits, e.g. 30 years, while glass slides might be retained for a shorter time, e.g. 10 years. Fresh tissue can be frozen and stored. Stored tissue may be useful for future clinical review, teaching, audit or research. In many countries, the subsequent use of stored tissue for non-clinical purposes is now subject to legal constraints.

PRINCIPLES OF MICROSCOPIC DIAGNOSIS

Diagnosis of malignancy

The main histological criteria for malignancy are metastasis, invasion, architectural changes and cytological features (Summary box 15.5).

Summary box 15.5

Microscopic features of malignancy

- Metastasis
- Invasion
 - Of surrounding tissue
 - Vascular
 - Perineural
- Architectural abnormalities
- Necrosis
- Numerous mitotic figures
- Atypical mitotic figures
- Nuclear abnormalities
 - Pleomorphism
 - Enlargement
 - Hyperchromaticity
 - Chromatin clumping
- Nucleolar enlargement and multiplicity

Metastasis (most often to lymph nodes or liver) is diagnostic of malignancy. Invasion of surrounding structures, perineural invasion (Figure 15.10) and vascular invasion (Figure 15.11) strongly suggest malignancy. Other microscopic features seen in

Figure 15.10 Perineural invasion. A nerve is almost completely surrounded by adenocarcinoma.

Figure 15.11 Vascular invasion. Aggregates of carcinoma cells are present within blood vessels. The tumour is poorly differentiated.

malignancy include architectural derangement, an increased number of mitotic figures, atypical mitoses, and necrosis (tissue death) (Figure 15.12). Microscopic changes at the cellular level (cytological changes) include nuclear enlargement, an increased nuclear:cytoplasmic ratio, nuclear pleomorphism (variation

Figure 15.12 An area of necrosis in a poorly differentiated carcinoma.

in shape) and nuclear hyperchromasia (dark colour) (Figure 15.13a). Multiplicity, irregularity and enlargement of nucleoli may also be seen (Figure 15.13b).

The criteria for a diagnosis of malignancy are influenced by the site and type of tissue. In general, epithelial cells must invade beyond their normal boundaries for malignancy to be diagnosed. The term 'dysplasia' usually indicates that microscopic features of carcinoma are present but invasion has not occurred, e.g. cervical intraepithelial neoplasia (CIN), colorectal dysplasia (Figure 15.14). However, the categorisation of some types of non-epithelial tumour (e.g. lymphoid, mesenchymal) as malignant may rely on cytological and architectural features rather than on invasiveness. In some cases, e.g. endocrine tumours, histological distinction between benign and malignant is impossible.

There are various causes of a false-positive diagnosis of malignancy. These include contamination of a specimen with tumour from elsewhere and interchanging of specimens. In addition, many conditions can mimic malignancy histologically. The risk of interpretative error by the histopathologist is reduced by

Figure 15.14 A colonic biopsy from a tubular adenoma with low-grade dysplasia. There is one non-dysplastic crypt (lower right corner). The remaining crypts show features of dysplasia, including nuclear stratification (multilayering) and nuclear hyperchromaticity (dark colour).

Figure 15.13 Cytological features of malignancy. (a) A high grade neuroendocrine carcinoma showing nuclear pleomorphism (variation in shape) and variation in nuclear size. There are several mitotic figures (arrows). (b) A malignant melanoma showing nuclear pleomorphism and prominent nucleoli (arrow) (courtesy of Dr E Husain, Aberdeen Royal Infirmary, UK).

thorough training, regular updating, discussion of difficult cases with colleagues, and avoidance of excessive workloads. The surgeon also helps to minimise such errors by supplying adequate clinical details. For example, a history of radiotherapy is essential because radiation effect can mimic malignancy. The histological changes in regenerating tissue, e.g. next to an ulcer, may also resemble malignancy (Summary box 15.6).

Summary box 15.6

Causes of false-positive diagnoses of malignancy

- Interchanged samples
- Contamination
- Interpretative error
- Treatment-induced change
- Ulceration

Histological types of malignancy

A malignant tumour showing features of epithelial differentiation, and typically arising in an epithelial layer, is a carcinoma. Other important types of malignancy include malignant melanoma (melanocytes) (Figure 15.13b), lymphoma (lymphoid cells) and sarcoma (mesenchymal cells). In most cases, further subclassification is possible. For example, a carcinoma can be classified as squamous cell carcinoma (which shows keratinisation) (Figure 15.15), adenocarcinoma (which shows tubule formation and/or mucin production) (Figure 15.16), neuroendocrine carcinoma/small cell carcinoma (Figure 15.13a) (usually requiring immunohistochemical confirmation), clear cell carcinoma (Figure 15.17), or one of many other types.

Prognostic factors for tumours

Tissue assessment is important for prognosis. Stage is generally the most important prognostic factor for carcinomas. The commonly used and internationally accepted Union Internationale Contre le Cancer (UICC) staging scheme depends heavily on the histopathological TNM category (pTNM), although the M (metastasis) category is usually evaluated clinically. Grade may also be prognostic and is usually determined microscopically.

Figure 15.15 A well-differentiated squamous cell carcinoma. Irregular nests of squamous cells with foci of keratinisation (arrows).

Figure 15.16 A well-differentiated adenocarcinoma. Gland formation (arrow) is obvious.

Figure 15.17 A metastatic clear cell carcinoma, composed of sheets of cells with clear cytoplasm. A tumour with this appearance is most likely to be of renal origin.

Low-grade/well-differentiated tumours resemble their normal tissue counterparts (Figures 15.15 and 15.16), whereas high-grade/poorly differentiated tumours do not (Figures 15.11 and 15.12). Other histological features associated with a poor prognosis include vascular invasion (Figure 15.11), perineural invasion (Figure 15.10) and positive resection margins. These factors differ in their prognostic value between tumour types and sites.

Inflammatory conditions

Acute inflammation is characterised by neutrophils (polymorphonuclear leukocytes) (Figure 15.18), and chronic inflammation by lymphocytes and plasma cells. Other inflammatory cells include eosinophils (Figure 15.19), mast cells and histiocytes. Granulomas (i.e. collections of epithelioid histiocytes) (Figure 15.20a and b) raise the possibility of mycobacterial infection, fungal infection, sarcoid, and a reaction to foreign material, among numerous other possible causes. Eosinophils in large numbers may reflect parasitic infection or allergy. Interpretation depends heavily on the site and clinical setting.

Other microscopic changes

Other abnormalities are also detectable by microscopy. Histopathologists may use specific terms for these changes. For

Figure 15.18 An acute inflammatory process characterised by numerous neutrophils. Note the typical multilobated nuclei in many cells (arrows).

Figure 15.19 An inflammatory lesion in which eosinophils, characterised by bright red cytoplasm, are predominant.

example, hyperplasia means an increase in cell number while hypertrophy refers to an increase in cell size. Atrophy encompasses a reduction in cell number and/or cell size. Metaplasia describes the change from one mature cell type to another, e.g. columnar metaplasia in the oesophagus (Barrett's oesophagus) where squamous epithelium is replaced by gastric or intestinal type epithelium. Necrosis refers to cell or tissue death.

ASSESSMENT

Light microscopy

Most tissue assessment depends on conventional light microscopy. Microscopes have several lenses with various powers of magnification, typically ranging from $\times 20$ to $\times 400$ or more. A low-power lens allows a sample to be scanned and its overall architecture to be assessed, while a high-power lens allows a closer and more detailed view (Figure 15.21a and b). A teaching arm and a camera can be attached to most microscopes (Figure 15.8). Polarisation can be used to detect foreign material (e.g. sutures) or to assess a special stain (e.g. Congo red).

Histological assessment

In a histological preparation, the microscopic structure of the tissue is preserved, allowing direct visualisation of architecture.

Figure 15.20 (a) A granuloma with necrosis, suggesting tuberculosis. Multinucleate giant cells of Langhan's type are also present (arrow). (b) A Ziehl-Neelsen stain (different case) shows numerous acid-fast bacilli.

Accordingly, the pathologist can see not only the characteristics of the cells that form the tissue, but also the way in which these cells are related to one another and the way in which different tissue compartments are arranged.

Cytological assessment

A cytological preparation consists of a sample of cells. Architecture cannot be determined, because intact tissue is absent or sparse (Figures 15.9 and 15.22a and b). Therefore, assessment relies mainly on the characteristics of the cells themselves. Accordingly, it may be difficult to diagnose malignancy because many of the criteria, particularly invasiveness, cannot be assessed. However, cytology has several potential advantages over histology (Summary box 15.7). A wider area may be sampled, and obtaining a specimen may be easier and less traumatic. Processing times are usually shorter and costs lower. Also, non-medical staff can be trained to report the cases, particularly cervical smears (Figure 15.9).

Screening

Screening programmes aim to detect and treat pre-malignant tissue changes, e.g. dysplasia, or early stage malignancy (rather than advanced disease). They may rely on cytology, histology or both. The largest is the cervical cancer programme, which uses cytology initially, with biopsy and histology follow up if

Figure 15.21 (a) Low-power view of an umbilical nodule. Glands are distributed irregularly through the tissue. (b) High-power view shows benign columnar epithelium lining the glands, favouring endometriosis over carcinoma.

Summary box 15.7

Cytology compared with histology

Advantages

- Wider area may be sampled
- Sampling may be less invasive
- Fast
- Cheap
- Can be interpreted by non-medical staff

Disadvantages

- Cannot assess tissue architecture
- Less amenable to further studies

appropriate. The breast cancer screening programmes may use cytology and/or histology, while the bowel cancer screening programmes and screening for cancer in ulcerative colitis rely on histology.

Specimen adequacy

There are several possible reasons for an inadequate specimen (Summary box 15.8). The operator may fail to sample the intended organ or lesion, or may take too few samples to detect a heterogeneous abnormality. A sample from the centre of a necrotic or ulcerated lesion might include no viable tissue.

Figure 15.22 (a) A cytology preparation of a pleural effusion. Numerous cells with atypical features are present. (b) Immunohistochemistry shows positive staining for carcinoembryonic antigen (CEA), favouring carcinoma over mesothelioma

Superficial biopsies from a carcinoma may fail to distinguish dysplasia (Figure 15.14) from invasive carcinoma. Cautery and crush artefact are sometimes severe enough to impede assessment. Cytology samples which have been spread too thickly can be uninterpretable.

Summary box 15.8

Reasons for an inadequate sample

Histology and cytology

- Failure to sample the intended organ or lesion
- Sample too limited
- Non-viable tissue

Histology

- Sample too superficial
- Cautery artefact
- Crush artefact

Cytology

- Thick smear

Deeper levels and extra blocks

The pathologist may request 'deeper levels', whereby the BMS cuts further into the paraffin block to obtain further sections. For example, deeper levels of an atypical but non-invasive epithelial

lesion might show foci of invasion, allowing carcinoma to be diagnosed. Extra blocks may be taken if a specimen has been sampled inadequately, e.g. if insufficient lymph nodes have been retrieved from a cancer resection specimen.

FURTHER WORK

Further diagnostic work is performed on a minority of histology specimens, and includes special stains and immunohistochemistry. *In situ* hybridisation, electron microscopy and polymerase chain reaction (PCR)-based methods are used less often. Some techniques can also be applied to cytology specimens (Summary box 15.9, Figure 15.22a and b).

Summary box 15.9

Additional techniques

- Special stains
- Immunohistochemistry
- *In situ* hybridisation
- Fluorescence *in situ* hybridisation (FISH)
- PCR-based techniques
- Electron microscopy

SPECIAL STAINS

A ‘special stain’ is a stain that is not routine. Immunohistochemical stains are conventionally excluded from this category. Some special stains demonstrate normal substances in increased quantities or in abnormal locations. The periodic acid–Schiff (PAS) stain demonstrates both glycogen and mucin, whereas a diastase periodic acid–Schiff (D-PAS) stain demonstrates mucin, e.g. in an adenocarcinoma. Perls Prussian blue stain demonstrates iron accumulation (Figure 15.23a and b), e.g. in haemochromatosis. A reticulin stain helps to demonstrate fibrosis (Figure 15.24a and b). Elastic stains also show fibrosis and can highlight blood vessels by outlining their elastic laminae. Special stains can also reveal the accumulation of abnormal substances, e.g. a Congo red stain for amyloid (Summary box 15.10).

Summary box 15.10

Common special stains

- PAS: glycogen, fungi
- D-PAS: mucin
- Perls Prussian blue: iron
- Reticulin: reticulin fibres, fibrosis
- van Gieson: collagen
- Congo red: amyloid
- Ziehl–Neelsen: mycobacteria

Figure 15.23 (a) Brown pigment in a biopsy. (b) A Perls stain is positive, indicating that the pigment is iron.

Figure 15.24 (a) A liver biopsy stained with haematoxylin and eosin (H&E) in which the severity of fibrosis cannot be determined. (b) A reticulin stain demonstrates fibrous bridges (arrows).

Hugo Schiff, 1834–1915, a German biochemist who worked in Florence, Italy.
Max Perls, 1843–1881, a pathologist of Giesen, Germany.
Congo red is sodium diphenylbisazobisnaphthylamine sulphonate.

Special stains are also useful for the diagnosis of infection. For example, a Ziehl–Neelsen stain demonstrates acid-fast bacilli, particularly mycobacteria, by staining them bright red in a blue background (Figure 15.20a and b). Mycobacteria cannot be seen on H&E slides. Other micro-organisms that may be detectable on H&E but are easier to see with a special stain include fungi (PAS or Grocott stain), protozoa (Giemsa stain) and spirochaetes (Warthin–Starry stain).

IMMUNOHISTOCHEMISTRY

Immunohistochemistry, which was introduced in the 1970s, has had a major impact on histopathological diagnosis. This technique detects a specific antigen using an antibody. The antibody is labelled with a dye and when bound to its target antigen is seen in the tissue section as a coloured stain, often brown (Figure 15.25). This allows the presence, tissue distribution and cellular localisation of an antigen to be determined. Immunohistochemistry can be applied to fixed and frozen tissue and to cytological preparations (Figure 15.22b). It is specific, safe, quick and relatively inexpensive. However, false-positive results can result from non-specific staining or from cross-reaction with similar antigens.

Figure 15.25 Diffuse immunohistochemical staining (brown) for a pan-cytokeratin marker in a malignancy, favouring carcinoma over other tumours.

Immunohistochemistry: tumour pathology

Immunohistochemistry has multiple applications in tumour pathology, including determination of cell type/direction of differentiation and elucidation of site of origin. Immunohistochemistry may also help to confirm neoplasia, determine the selection of treatment and refine prognostic predictions (Summary box 15.11).

Various immunohistochemical stains are used to detect cell type. Cytokeratins are expressed by epithelial cells. Cytokeratin positivity favours carcinoma (Figure 15.25) over other malignancies. Lymphoid markers include the panlymphoid marker CD45, the T-cell marker CD3 and the B-cell marker CD20. Markers of melanocytic differentiation include S100, MelanA and HMB45. Chromogranin, synaptophysin and CD56 stain neuroendocrine tumours such as carcinoid and small cell carcinoma. A gastrointestinal stromal tumour (GIST) typically expresses CD117 (Figure 15.26a and b) and DOG-1. Endothelial cell markers

Summary box 15.11

Some immunohistochemical stains used for tumours

- Cell type/site of origin:
 - Epithelial (carcinoma): cytokeratins
 - Lymphoid (lymphoma): CD45, CD3, CD20
 - Melanocytic (melanoma): S100
 - Neuroendocrine: synaptophysin, chromogranin
 - Vascular: CD31
 - Myoid: desmin, actin
- Site of origin/cell type:
 - Prostate: prostate-specific antigen (PSA)
 - Lung: thyroid transcription factor-1 (TTF-1)
 - Thyroid: thyroglobulin
 - Colorectum: cytokeratin 20 (CK20), CDX2
 - Liver: HepPar
 - Gastrointestinal stromal tumour (GIST): CD117, DOG-1
- Prognosis and treatment:
 - Breast carcinoma: receptors (ER, PR, HER2)
 - Endocrine tumours: Ki67 proliferative index

Figure 15.26 (a) A metastatic tumour composed of spindle cells. Gastrointestinal stromal tumour (GIST) was suspected. (b) Positive immunohistochemistry for CD117, confirming GIST.

include CD31, which may highlight vascular invasion or confirm a diagnosis of vascular neoplasia.

The site of origin of a metastatic tumour may be suggested by H&E appearances. For example, a clear cell carcinoma (Figure 15.17) is most likely to be of renal origin while an adenocarcinoma has several possible sources. Immunostains may provide further information. Some are highly specific, e.g. prostate-specific antigen (PSA) and thyroglobulin. Others are somewhat less specific, e.g. thyroid transcription factor-1 (TTF-1), which favours bronchogenic origin; HepPar, which favours hepatocellular origin; and cytokeratin 20 and CDX2 which are typically expressed by colorectal carcinoma. Carcinoembryonic antigen (CEA) is seen in several types of carcinoma (Figure 15.22a and b), while CA125 is a marker for ovarian and other gynaecological tumours. However, some tumours (especially poorly differentiated examples) do not conform to the typical patterns. Therefore, the clinical picture and imaging results must always be taken into account.

Less often, immunohistochemistry is used to help confirm malignancy. For example, light chain restriction (expression of only one immunoglobulin light chain) in lymphoid proliferations suggests clonality and favours neoplasia.

Immunohistochemistry may also play a role in the selection of treatment and in predicting prognosis. For example, carcinomas of the breast are routinely assessed for oestrogen receptor (ER), progesterone receptor (PR) and HER2 status, while lymphomas are typically subjected to a comprehensive panel of markers. Assessment of the Ki67 proliferative index enhances the management of endocrine tumours and some other neoplasms (Figure 15.27).

Figure 15.27 Immunohistochemistry for Ki67. The proliferative index is approximately 10 per cent.

Immunohistochemistry: infections and other applications

There are antibodies to many infective agents, including cytomegalovirus (CMV), Epstein–Barr virus (EBV), herpes simplex virus, human herpes virus 8 (HHV8), hepatitis B virus and *Helicobacter pylori*. Some of these, e.g. EBV and HHV8, cannot be demonstrated by H&E and require immunohistochemistry or other techniques for their detection.

Immunohistochemistry can also be used to study immunoglobulin and complement expression (e.g. in lymphomas or

renal biopsies), to assess the abnormal accumulation of various proteins such as alpha-1-antitrypsin (A1AT), to characterise amyloid, and to screen for mismatch repair gene mutations (Summary box 15.12).

Summary box 15.12

Uses of immunohistochemistry

- Cell type
- Neoplasia:
 - Differentiation
 - Determination of site of origin
 - Confirmation of neoplasia
 - Selection of treatment
 - Screening for mutations
 - Prognosis
- Micro-organisms
- Other:
 - Amyloid
 - Immunoglobulins
 - Complement

ELECTRON MICROSCOPY

Electron microscopy allows tissue to be visualised at very high magnification, e.g. $\times 1000$ to $\times 500\,000$. It may help to decide the lineage of a non-neoplastic or neoplastic cell in difficult cases, and may help to determine the nature of abnormal deposits, e.g. in renal disease. Unfortunately, it is time-consuming, labour intensive and expensive, and is now used very selectively.

IN SITU HYBRIDISATION

In situ hybridisation (ISH) uses a labelled oligonucleotide probe targeted at a specific RNA or DNA sequence. It can be performed on fixed or fresh tissue sections, allowing the presence or absence of a particular sequence and its location to be determined. Viral genomes, e.g. EBV (Figure 15.28), CMV and human papillomavirus, can be detected using this approach.

Figure 15.28 *In situ* hybridisation for Epstein–Barr virus (EBV) showing extensive nuclear positivity (black nuclei) in a gastric adenocarcinoma.

Interphase cytogenetics

This technique is relatively safe and fast and has largely replaced conventional cytogenetics for the analysis of chromosomal changes. It relies mainly on fluorescent *in situ* hybridisation (FISH) (named after the probe's fluorescent label), but also silver *in situ* hybridisation (SISH) and other methods. Fresh and fixed histological material and cytological preparations can be used, the latter typically yielding better results. The probe can target centromeres in order to assess numerical or structural chromosomal abnormalities or can target specific genes.

The technique is used (alongside immunohistochemistry) to detect HER2 amplification in breast cancer and, more recently, in advanced gastric cancer. The results inform the selection of therapy. Other uses include detection of chromosomal gains, losses, and translocations in tumours (e.g. haematological malignancies) and non-neoplastic conditions (e.g. trisomy 23) and loss of specific gene regions in tumours (e.g. 1p and 19q in oligodendrogliomas). Some of these changes can also be detected using PCR, which is more expensive.

POLYMERASE CHAIN REACTION-BASED AND RELATED TECHNIQUES

The PCR amplifies DNA, yielding millions of copies from a single copy of a selected target. The amplified DNA is detected using various techniques, e.g. electrophoresis. RNA can also be amplified, using the technique of reverse transcriptase polymerase chain reaction (RT-PCR). PCR is highly sensitive, fast and safe. However, it is expensive and has a high chance of contamination with DNA from outside sources. PCR can be performed on non-tissue samples (e.g. peripheral blood) and on homogenised fresh tissue. DNA or RNA extracted from formalin fixed tissue may be of lower quality but is also widely used. PCR has many clinical applications, particularly the detection of gene mutations and amplifications and the confirmation of clonality in tumours (Summary box 15.13).

Summary box 15.13

Clinical applications of PCR to tissue samples

- Mutational analysis
- Clonality
- Loss of heterozygosity
- Chromosomal abnormalities
- Detection of micro-organisms

Detection of mutations

Mutational analysis includes screening methods and direct sequencing. Direct sequencing for mutations requires DNA, which has usually been amplified using PCR.

A germline mutation may predispose a patient to a specific disease or tumour. If the mutation is known, a sample of blood or tissue can be used to test patients and screen their families for the disease. For example, most patients with hereditary haemochromatosis are homozygous for a mutation of the *HFE* gene. Another example is colorectal carcinoma which can harbour germline or sporadic mutations of the *APC* gene (Figure 15.29) or of mismatch repair genes (*MLH1*, *MSH2*, *MSH6*, *PMS2*). Immunohistochemistry on fixed tumour tissue can be used to screen for mismatch repair gene defects (Figure 15.30), allowing

Figure 15.29 Mutation analysis of the *APC* gene. Several different tumours have been tested for mutation of the *APC* gene by polymerase chain reaction (PCR). Samples 1 and 2 (colorectal cancers) show loss of part of the *APC* gene resulting in smaller sized PCR products. All samples underwent sequence analysis, and point mutations (resulting in sequence change without loss of DNA) were identified in samples 5 and 7 (also colorectal cancers) (courtesy of Professor M Ilyas, Nottingham University, UK).

Figure 15.30 Immunohistochemical screening for mismatch repair gene mutations in a carcinoma. (a) Nuclear *MLH1* expression is retained (arrows showing positively staining brown neoplastic nuclei). (b) In contrast, *MSH2* expression is lost, suggesting a mismatch repair gene abnormality.

a subsequent decision about direct sequencing and family screening to be made.

Analysis of mutations in tumour tissue can also enhance treatment plans. For example, detection and characterisation of KIT and PDGFRA gene mutations in GIST can help confirm the diagnosis, refine prognostic predictions, and assist with selection of drug therapy for advanced lesions. K-RAS mutational analysis in metastatic colorectal carcinoma may help predict response to anti-EGFR chemotherapy.

Clonality

Clonal immunoglobulin heavy chain (IgH) gene rearrangements in B-cell proliferations and clonal T-cell receptor gene rearrangements in T-cell proliferations favour lymphoma over reactive proliferations. These rearrangements can be detected using PCR.

Loss of heterozygosity

PCR-based methods are the most reliable for detection of loss of heterozygosity. FISH can yield similar information and is quicker and cheaper.

Micro-organisms

PCR can be used to amplify DNA from micro-organisms, e.g. *Mycobacterium tuberculosis*. It can be performed on formalin-fixed tissue, but the reliability of this approach is variable.

AUTOPSY

In the past, advances in medical knowledge were sometimes based on autopsy findings. Autopsies remain very useful for

medical education and audit. In the UK, there are two types of autopsy. The first is the coroner's post-mortem, when the coroner has decided that there is a legal need to establish the cause of death. The second is the hospital autopsy, which requires relatives' consent. This type occurs less frequently now than in the past. In most cases, all organs are examined. Tissue may be retained for further examination if appropriate and if permitted by ethical guidelines.

SUMMARY

Analysis of tissue has played a steadily more important role in clinical management over the past few decades. Accordingly, pathologists work more closely with surgeons and their teams than ever before, and the interaction is greatly enhanced when the surgeon appreciates the value and limitations of tissue diagnosis.

ACKNOWLEDGEMENT

The author is grateful to Professor MT Sheaff for assistance with the sections on cytology.

Preoperative preparation

LEARNING OBJECTIVES

To be able:

- To organise preoperative care and the operating list

To understand:

- Surgical, medical and anaesthetic aspects of assessment

- How to optimise the patient's condition
- How to take consent
- How to organise an operating list

INTRODUCTION

Many patients requiring inpatient elective procedures arrive in hospital on the day of surgery. Therefore a 'preoperative assessment' clinic may be the only opportunity to gather all information, optimise comorbidities, and then organise anaesthetic, surgical and postoperative care before surgery actually takes place.

First, a history should be taken, examination performed and the relevant investigations ordered. Focus should then turn to the specific problems uncovered. All sources of information should be exploited including the patient, the general practitioner (GP) and hospital records. GPs can offer valuable help by monitoring chronic conditions, adjusting medications, facilitating weight reduction, as well as encouraging the patient to take exercise and stop smoking.

Patients with severe comorbidities should be referred to the relevant specialist to quantify the risks and to take appropriate measures to minimise operative morbidity. Surgery cannot be made risk free, but risks must be known so that the patient can make an informed decision. Patients should be given advice on when they should be nil by mouth (NBM) and what to do about regular medications and premedication.

Finally, a plan for the operating list should be drawn up and all those involved in making the list run smoothly should be informed (Summary box 16.1).

Summary box 16.1

Preoperative plan for the best patient outcomes

- Gather and record all relevant information
- Optimise patient condition
- Choose surgery that offers minimal risk and maximum benefit
- Anticipate and plan for adverse events
- Inform everyone concerned

PATIENT ASSESSMENT

The aim of a structured assessment is to learn to look actively for risks and manage them so as to enable surgery to go ahead safely. Assessment is done by the surgical, nursing team and/or anaesthetic team at outpatient or inpatient setting.

History taking

A standard history should be taken focusing on the patient's hopes and expectations (open questions and then listen), then on specific questions aimed at clarifying the diagnosis and severity of symptoms (closed questions). A set of fixed questions are needed to determine 'fitness' for surgery. Surgery-specific symptoms (including features not present), onset, duration and exacerbating and relieving factors should also be documented.

For each system a relevant history should be taken, noting what problems have occurred and when (Table 16.1). These should include a cardiovascular history focusing on high blood pressure, chest pains, palpitations, syncope, dyspnoea and poor exercise tolerance. Similarly, respiratory problems should be explored further if there is history of smoking, productive cough, wheeze, dyspnoea, hoarseness of voice or stridor present. Increasing severity of symptoms generally indicates worsening of the condition.

The history of past surgery and anaesthesia can reveal problems that may present during current hospitalisation (e.g. intra-abdominal adhesions and suxamethonium apnoea). The use of recreational drugs and alcohol consumption should be noted as they are known to be associated with adverse outcomes. Check for allergies and risk factors for deep vein thrombosis (DVT). Social history, ability to communicate and mobility are important in planning rehabilitation after surgery (Summary box 16.2).

Table 16.1 Key topics in past medical history.

Cardiovascular	Ischaemic heart disease: angina, myocardial infarction Hypertension Heart failure Dysrhythmia Peripheral vascular disease Deep vein thrombosis and pulmonary embolism
Respiratory	Chronic obstructive pulmonary disease Asthma Respiratory infections
Gastrointestinal	Peptic ulcer disease and gastro-oesophageal reflux Liver disease
Genitourinary tract	Urinary tract infection Renal dysfunction
Neurological	Epilepsy Cerebrovascular accidents and transient ischaemic attacks Psychiatric disorders Cognitive function
Endocrine/metabolic	Diabetes Thyroid dysfunction Pheochromocytoma Porphyria
Locomotor system	Osteoarthritis Inflammatory arthropathy, such as rheumatoid arthritis
Other	Human immunodeficiency virus Hepatitis Tuberculosis Malignancy Allergy
Previous surgery	Problems encountered Family history of problems with anaesthesia

Those in bold font need recording even when negative.

Summary box 16.2

Principles of history taking

- Listen: What is the problem? (Open questions)
- Clarify: What does the patient expect? (Closed questions)
- Narrow: Differential diagnosis (Focused questions)
- Fitness: Comorbidities (Fixed questions)

Examination

Patients should be treated with respect and dignity, receive a clear explanation of the examination undertaken and kept as comfortable as possible (Table 16.2). A chaperone should always be present, especially for intimate examinations.

Table 16.2 Medical examination.

General	Anaemia, jaundice, cyanosis, nutritional status, sources of infection (teeth, feet, leg ulcers)
Cardiovascular	Pulse, blood pressure, heart sounds, bruits, peripheral oedema
Respiratory	Respiratory rate and effort, chest expansion and percussion note, breath sounds, oxygen saturation
Gastrointestinal	Abdominal masses, ascites, bowel sounds, hernia, genitalia
Neurological	Consciousness level, cognitive function, sensation, muscle power, tone and reflexes
Airway assessment	

Along with routine cardiovascular examination one should look specifically for evidence of cardiac failure (raised jugular venous pressure (JVP), fine crackles, gallop rhythm), peripheral vascular disease (loss of peripheral pulses, ulcerations) and valvular heart disease with characteristic murmurs (e.g. ejection systolic in aortic stenosis, pansystolic in tricuspid regurgitation and mid-diastolic murmur in mitral stenosis heard at the respective area on auscultation) in symptomatic patients.

Presence of a high respiratory rate, reduced air entry, crepitations and ronchi indicate respiratory problems. History of dyspnoea along with examination findings of tachycardia, raised JVP, tricuspid regurgitation, hepatomegaly and oedema of the feet will indicate severe respiratory disease with pulmonary hypertension and right ventricular failure (Summary box 16.3).

Summary box 16.3

Examination

- General: Positive findings even if not related to the proposed procedure should be explored
- Surgery related: Type and site of surgery, complications which have occurred due to underlying pathology
- Systemic: Comorbidities and their severity
- Specific: For example, suitability for positioning during surgery

Examination specific to surgery

At preoperative assessment, the clinical findings, site, side, specific imaging or investigation findings related to the pathology for which the surgery is proposed should be noted. Suitability of the patient for the proposed surgical option and vice versa should also be assessed. For example, laparoscopic procedures are less invasive and are therefore preferred in most. However not all patients can tolerate a pneumoperitoneum, head-down positioning, etc.

Surgery puts the patient's life 'at risk' and so the benefit of the procedure should outweigh the risk of surgery. Type of surgery along with patient comorbidities determine perioperative risks, for example perioperative mortality in major surgery, such as that of aortic aneurysm repair in the UK is 4–5 per cent.

Sources of potential bacteraemia can compromise surgical results especially if artificial material is implanted, such as in

joint replacement surgery or arterial grafting. Check for and treat infections in the preoperative period (e.g. infected toes, pressure sores, teeth and urine; screen the patients for methicillin-resistant *Staphylococcus aureus* colonisation).

Investigations

Minor and intermediate surgery generally requires no routine investigations unless the patient has comorbidities. The UK National Institute of Health and Clinical Excellence (NICE) guidelines lay out the investigations needed for various categories of surgery (Summary box 16.4).

Summary box 16.4

Investigations needed

- Type of surgery: Major surgery can lead to organ system dysfunction so needs most investigations
- Patient: For example, sickle cell test for patient with Afro-Caribbean origin
- Comorbidities: For example, peak flow rates for severe asthmatics

- **Full blood count.** A full blood count (FBC) is needed for major operations, in the elderly and in those with anaemia or pathology with ongoing blood loss. A sickle cell test is needed in any patient of Afro-Caribbean origin.
- **Urea and electrolytes.** Urea and electrolytes (U&E) are needed before all major operations, in most patients over 60 years of age especially with cardiovascular, renal and endocrine disease or if significant blood loss is anticipated. It is also needed in those on medications which affect electrolyte levels, e.g. steroids, diuretics, digoxin, NSAIDs (non-steroidal anti-inflammatory drugs), intravenous fluid or nutrition therapy.
- **Electrocardiography.** Electrocardiography (ECG) is required for those patients aged over 60 years, cardiovascular, renal and cerebrovascular involvement, diabetes and in those with severe respiratory problems.
- **Clotting screen.** If a patient has a history suggestive of bleeding diathesis, liver disease, eclampsia, cholestasis or has a family history of bleeding disorder, or is on antithrombotic or anticoagulant agents, then coagulation screening will be needed. However, the effects of antiplatelet agents, low molecular weight heparins and newer agents affecting factor Xa cannot be measured by routine laboratory tests.
- **Chest radiography.** A chest x-ray is not required unless the patient has a significant cardiac history, cardiac failure, severe chronic obstructive pulmonary disease (COPD), acute respiratory symptoms, pulmonary cancer, metastasis or effusions, or is at risk of tuberculosis.
- **Urinalysis.** Dipstick testing of urine should be performed on all patients to detect urinary infection, biliuria, glycosuria and inappropriate osmolality.
- **β -Human chorionic gonadotrophin.** Pregnancy needs to be ruled out in all women of childbearing age.
- **Blood glucose and HbA1c.** These should be performed in patients with diabetes mellitus and endocrine problems. HbA1c indicates how well diabetes has been controlled over a longer duration.

- **Arterial blood gases.** This test allows detailed assessment of severe respiratory conditions and acid-base disturbances.
- **Liver function tests.** These are indicated in patients with jaundice, known or suspected hepatitis, cirrhosis, malignancy or patients with poor nutritional reserves.
- **Other investigations.** Further relevant investigations should be undertaken to assess capacity of specific organ system and risks associated. Specialist radiological views and recent imaging are sometimes required. If imaging is going to be needed during surgery then this needs to be planned in advance.

SPECIFIC PREOPERATIVE PROBLEMS, REFERRALS AND MANAGEMENT

Specific medical problems encountered during preoperative assessment should be corrected to the best possible level. Many patients with severe disease will need to be referred to specialists; the referral letter should include all the details including history, examination and investigation results (Summary box 16.5).

Summary box 16.5

Preoperative management of patients with systemic disease

- Capacity: Baseline organ function capacity should be assessed
- Optimisation: Medication, lifestyle changes, specialist referral will improve organ capacity
- Alternative: Minimally impacting procedure, appropriate postoperative care will improve outcomes
- Theatre preparations: Timing, teamwork, special instruments and equipment

Cardiovascular disease

Patients who can climb a flight of stairs without getting short of breath or having chest pain, or indeed stopping have a lower risk of perioperative morbidity and mortality of cardiovascular origin than those who cannot.

At preoperative assessment, it is important to identify the patients who have a high perioperative risk of myocardial infarction (MI) and make appropriate arrangements to reduce this risk. These patients include those who have suffered coronary artery disease, congestive cardiac failure, arrhythmias, severe peripheral vascular disease, cerebrovascular disease or renal failure, especially if they are undergoing intra-abdominal or intrathoracic surgery.

In patients with ischaemic heart disease (IHD), the left ventricular status can be evaluated using a stress test. The test has a high negative predictive value and a low positive predictive value. In other words, if the test is negative, then the patient is unlikely to have IHD and if it is positive the chances of the patient actually having IHD is not high.

For patients with symptomatic valvular heart disease or poor left ventricular function, an echocardiography should be performed. Pressure gradients across the valves, dimensions of the chambers and contractility can be determined using echocardiography; an ejection fraction of less than 30 per cent is associated with poor patient outcomes.

Cardiopulmonary exercise testing when performed provides a non-invasive assessment of combined pulmonary, cardiac and circulatory function.

The patient should be referred to a cardiologist if:

- A murmur is heard and the patient is symptomatic.
- The patient is known to have poor left ventricular function or cardiomegaly.
- Ischaemic changes can be seen on ECG even if patient is not symptomatic (silent MI).
- There is an abnormal rhythm on the ECG, tachy/bradycardia or a heart block that may lead to cardiovascular compromise.

Hypertension, ischaemic heart disease and stents

Prior to elective surgery, blood pressure should be controlled to near 160/90 mmHg. If a new antihypertensive is introduced, a stabilisation period of at least 2 weeks should be allowed.

Patients with angina which is not well controlled should be investigated further by a cardiologist (Figure 16.1). Some of these patients may need thrombolysis, percutaneous coronary balloon angioplasty, statins, coronary artery bypass surgery or coronary stenting prior to non-cardiac surgery.

Elective surgery should be postponed for three to six months after a proven myocardial infarct to reduce the risk of perioperative reinfarction.

Patients may have had coronary stents inserted for IHD and should be asked about effectiveness of the treatment, concurrent antiplatelet medications, e.g. clopidogrel and/or aspirin. Risk of stent thrombosis with consequences of MI and death is reduced if elective surgery is delayed until after dual antiplatelet therapy is stopped (about 6 weeks after bare metal and 12 months after drug-eluting stent insertion).

If surgery cannot be postponed and the risk of significant perioperative bleeding is low, the dual antiplatelet therapy can be continued during surgery. If surgery poses a significant risk (spinal, intracranial, cardiac, posterior chamber of eye and pros-

tate surgery), clopidogrel may be stopped and aspirin continued, however, cardiology opinion will need to be sought.

Most long-term cardiac medications should be continued over the perioperative period. Ongoing treatment with beta-blockers and statins is known to reduce perioperative morbidity and mortality.

Dysrhythmias

In patients with atrial fibrillation, beta-blockers, digoxin or calcium channel blockers should be started preoperatively (or continued if the patient is already on the treatment) in order to control the rate and possibly rhythm. Cardiac output can increase by 15 per cent if sinus rhythm is restored. This reduces the risk of perioperative myocardial ischaemia and infarction. Warfarin in patients with atrial fibrillation should be stopped 5 days preoperatively to achieve an INR (international normalised ratio) of 1.5 or less, which is safe for most surgery; an alternative anticoagulation is not required in the perioperative period.

Implanted pacemaker and cardiac defibrillator checks and appropriate reprogramming should be done preoperatively. Bipolar diathermy activity during surgery may be sensed by the pacemaker as ventricular fibrillation. Therefore, cardioversion and overpace modes may be turned off (switch on after surgery) or converted to 'ventricle paced, not sensed with no response to sensing' (VOO) mode especially if bipolar diathermy cannot be used.

Symptomatic heart blocks and asymptomatic second- (Mobitz II) and third-degree heart blocks, if discovered at preoperative assessment clinic, will need cardiology consultation and temporary pacemaker insertion.

Figures 16.2 and 16.3 illustrate two cases requiring preoperative optimisation.

Valvular heart disease

While anaesthetic management is altered to achieve haemodynamic stability in moderate valvular diseases, the patients with severe aortic and mitral stenosis may benefit from valvuloplasty before undergoing elective non-cardiac surgery. Appropriate referral to anaesthetist and cardiologists should be made.

Figure 16.1 Preoperative electrocardiogram of a patient who complained of chest pain the previous day showing recent transmural anterior myocardial infarction with Q waves and ST elevation.

Figure 16.2 Routine preoperative electrocardiogram in an 83-year-old patient with no symptoms other than lethargy for the last three months. This shows complete heart block with dissociated P waves and QRS complexes, requiring preoperative pacing.

Figure 16.3 Atrial flutter.

In patients with mechanical heart valves, warfarin needs to be stopped for 5 days before surgery, and an infusion of unfractionated heparin started when the INR falls below 1.5. The activated partial thromboplastin time (APTT) should be monitored to keep it at 1.5 times normal and the infusion is then stopped 2 hours before surgery. Heparin and warfarin should be started in the postoperative period and heparin is stopped when the full effect of warfarin is realised.

Anaemia and blood transfusion

Patients found to be anaemic at preoperative assessment should be treated with iron and vitamin supplements. Chronic anaemia is well tolerated in the perioperative period; however, if the patient is undergoing a major procedure, preoperative transfusion may be considered below a haemoglobin level of 8 g/dL. If excessive bleeding is expected, then a preoperative 'group and save' should be performed and an appropriate number of units of blood crossmatched.

Jehovah's Witness patients usually refuse blood transfusion; the legal document as to which blood and products they will accept or refuse should be made available and abided by (e.g. cell salvage, reinfusion from drains may be acceptable).

Respiratory disease

The patient's current respiratory status should be compared with their 'normal state'. Note should be made of regular treatment, records of peak expiratory flow rates (PEFR), use of steroids, home oxygen and continuous positive airway pressure (CPAP) ventilation; check for evidence of right heart failure.

Encourage the patients to be compliant with the medications, take exercise and a balanced diet, and stop smoking.

Administration of regular medications with an additional dose of bronchodilators given just prior to surgery will reduce the chances of untoward events. Patients taking more than 10 mg of prednisolone and undergoing high-risk surgery will need perioperative steroid supplements.

Regional anaesthetic techniques and less invasive surgical options should be considered in severe cases. Elective surgery should be postponed until acute exacerbations are treated.

Refer the patient to respiratory physicians if:

- There is a severe disease or significant deterioration from usual condition.
- Major surgery is planned in a patient with significant respiratory comorbidities.
- Right heart failure is present: dyspnoea, fatigue, tricuspid regurgitation, hepatomegaly and oedema of the feet.
- The patient is young with COPD (indicates a rare and life-threatening condition).

Pulmonary function tests will indicate the type and severity of the disease, as well as response to the treatment.

Smoking

Information should be provided to indicate perioperative risks associated with smoking. Stopping smoking reduces carbon monoxide levels and the patient is better able to clear sputum.

Asthma

It is important to establish the severity of the asthma, precipitating causes, frequency of bronchodilator and steroid use, PEFR (peak expiratory flow rate) and any previous intensive care unit admissions. Patients should continue to use their regular inhalers until the start of anaesthesia. Brittle asthmatics may also need extra steroid cover.

Chronic obstructive pulmonary disease

Patients on steroid treatment, or oxygen therapy, or who have a forced expiratory volume in the first second (FEV1) less than 30 per cent of predicted value (for age, weight and height) have severe disease and may have respiratory failure in the postoperative period. Preoperative chest x-ray or scans are useful in patients with known emphysematous bullae, pulmonary cancer, metastasis or effusions. Patients with significant COPD who are undergoing major surgery will need to be referred to the respiratory physicians for optimisation of their condition.

An arterial blood gas analysis may also be useful as it can give an indication of carbon dioxide retention. This is associated with an increased risk of perioperative respiratory complications.

Infection

Elective surgery should be postponed if the patient has a chest infection. It should be treated with antibiotics and physiotherapy and the operation rescheduled after 4–6 weeks.

Gastrointestinal disease

Nil by mouth and regular medications

Patients are advised not to take solids within 6 hours and clear fluids (isotonic drinks and water) within 2 hours before anaesthetic to avoid the risk of acid aspiration syndrome. Infants are allowed a clear drink up to 2 hours, mother's milk up to 3 hours and cow or formula milk up to 6 hours before anaesthetic.

If the surgery is delayed, oral (until 2 hours of surgery) or intravenous fluids should be started especially in the vulnerable groups of patients, e.g. children, elderly and diabetics.

Patients can continue to take their specified routine medications with sips of water in the nil by mouth period.

Regurgitation risk

Patients with hiatus hernia, obesity, pregnancy and diabetes are at high risk of pulmonary aspiration even if they have been NBM before elective surgery. Clear antacids, H2-receptor blockers, e.g.

A Jehovah's Witness is a member of a millenarian fundamentalist Christian sect founded in America in 1884. They have their own translation of the Bible which they interpret literally and do not allow blood transfusion.

ranitidine or proton pump inhibitors, e.g. omeprazole, may be given at the appropriate time in the preoperative period.

Liver disease

In patients with liver disease, the cause of the disease needs to be known, as well as any evidence of clotting problems, renal involvement, and encephalopathy. Elective surgery should be postponed until any acute episode has settled (e.g. cholangitis). The blood tests which need to be performed are liver function tests, coagulation, blood glucose, urea and electrolyte levels. The presence of ascitis, oesophageal varices, hypoalbuminaemia, sodium and water retention should be noted as all these can influence choice and outcomes of anaesthesia and surgery.

Genitourinary disease

Renal disease

Underlying conditions leading to chronic renal failure, such as diabetes mellitus, hypertension and ischaemic heart disease, should be stabilised before elective surgery. Appropriate measures should be taken to treat acidosis, hypocalcaemia and hyperkalaemia of greater than 6 mmol/L. Arrangements should be made to continue peritoneal or haemodialysis until a few hours before surgery. After the final dialysis before surgery, a blood sample should be sent for FBC and U&E.

Chronic renal failure patients often suffer chronic microcytic anaemic that is well tolerated, therefore preoperative blood transfusion is usually not necessary.

Acute renal failure can present with acute surgical problems, for example bowel obstruction needing emergency surgery. In such patients, simultaneous medical and surgical treatment and critical care unit support will be needed in the perioperative period.

Urinary tract infection

Uncomplicated urinary infections are common in women, while outflow uropathy with chronically infected urine is common in men. These infections should be treated before embarking on elective surgery where infection carries dire consequences, e.g. joint replacement. For emergency procedures, antibiotics should be started and care taken to ensure that the patient maintains a good urine output before, during and after surgery.

Endocrine and metabolic disorders

Malnutrition

Body mass index (BMI) is weight in kilograms divided by height in metres squared. A BMI of less than 18.5 indicates nutritional impairment and a BMI of less than 15 is associated with significant hospital mortality. Nutritional support for a minimum of 2 weeks before surgery is required to have any impact on subsequent morbidity.

If a patient is unlikely to be able to eat for a significant period, arrangements should be made by the preoperative assessment team to start nutritional support in the immediate postoperative phase.

Obesity

Morbid obesity is defined as BMI of more than 35 and is associated with increased risk of postoperative complications. Patients should be made aware of risks involved and advised on healthy eating and taking regular exercise.

Associated sleep apnoea can be predicted by using a clinical scoring system of perioperative sleep apnoea prediction (P-SAP) score or sleep apnoea studies. Patients should be asked to continue to use a CPAP device for obstructive sleep apnoea and cholesterol-reducing agents in the perioperative phase.

If possible, delay surgery until the patients are more active and have lost weight. If this fails, prophylactic measures need to be taken (such as preventative measures for acid aspiration and deep vein thrombosis (DVT)) and associated risks need to be explained prior to the surgery.

Diabetes mellitus

Diabetes and associated cardiovascular and renal complications should be controlled to as near normal level as possible before embarking on elective surgery. Any history of hyper- and hypoglycaemic episodes, and hospital admissions, should be noted. HbA1c levels should be checked. Lipid-lowering medication should be started in patients who are in a high-risk group of cardiovascular complications of diabetes.

Patients with diabetes should be first on the operating list and if they are operated on in the morning advised to omit the morning dose of medication and breakfast. Though tight control of blood sugar is not needed, the patient's blood sugar levels should be checked every 2 hours. For those on the afternoon list, breakfast can be given with half their regular dose of insulin (or full-dose oral anti-diabetic agents) and then managed with regular blood sugar checks as above. An intravenous insulin sliding scale should be started for insulin-dependent diabetes mellitus undergoing major surgery or if blood sugar is difficult to control for other reasons.

Adrenocortical suppression

Patients receiving oral adrenocortical steroids should be asked about the dose and duration of the medication in view of supplementation with extra doses of steroids perioperatively to avoid an Addisonian crisis.

Coagulation disorders

Thrombophilia

Patients with a strong family history or previous personal history of thrombosis should be identified. They will need thromboprophylaxis in the perioperative period (Table 16.3).

The progesterone-only pill should be continued, however, the risks of continuing the combined pill (slight increased risk of significant thrombosis) should be weighed against the risks of an unplanned pregnancy. Hormone replacement therapy (HRT) should be stopped 6 weeks prior to surgery.

Patients with a low risk of thromboembolism can be given thromboembolism-deterrent stockings to wear during the perioperative period. High-risk patients with a history of recurrent DVT, pulmonary embolism (PE) and arterial thrombosis will be on warfarin. This should be stopped before surgery and replaced by low molecular weight heparin or factor Xa inhibitors. Each hospital has guidelines which advise what type of DVT prophylaxis should be used for each type of surgery.

Neurological and psychiatric disorders

In patients with a history of stroke, pre-existing neurological deficit should be recorded. These patients may be on antiplatelet agents or anticoagulants. If it is felt that the neurological

Table 16.3 Risk factors for thrombosis.

Age >60 years
Obesity: body mass index (BMI) >30 kg/m ²
Trauma or surgery (especially of the abdomen, pelvis and lower limbs), anaesthesia >90 minutes
Reduced mobility for more than 3 days
Pregnancy/puerperium
Varicose veins with phlebitis
Drugs, e.g. oestrogen contraceptive, hormone replacement therapy (HRT), smoking
Known active cancer or on treatment, significant medical comorbidities, critical care admission
Family/personal history of thrombosis, e.g. deficiencies in antithrombin III, protein S and C

and cardiovascular thrombotic risks are low, antiplatelet agents should be withdrawn (7 days for aspirin, 10 days for clopidogrel). If the thrombotic risks are perceived to be high and the patient is undergoing surgery with a high risk of bleeding, aspirin alone should be continued.

Anticonvulsant and antiparkinson medication is continued perioperatively to help early mobilisation of the patient.

Lithium should be stopped 24 hours prior to surgery; blood levels should be measured to exclude toxicity. The anaesthetist should be informed if patients are on psychiatric medications such as tricyclic antidepressants or monoamine oxidase inhibitors, as these may interact with anaesthetic drugs.

Musculoskeletal and other disorders

Rheumatoid arthritis can lead to unstable cervical spine with the possibility of spinal cord injury during intubation. Therefore, flexion and extension lateral cervical spine x-rays should be obtained (Figures 16.4 and 16.5).

Assessment of severity of renal, cardiac valvular and pericardial involvement, as well as restrictive lung disease, should

**Figure 16.4** Extension view of cervical spine in patient with rheumatoid arthritis.**Figure 16.5** Flexion view in the same patient as in Figure 16.4. Note the huge increase in the atlantodens interval, implying significant instability at this level.

be carried out. Rheumatologists will advise on steroids and disease-modifying drugs so as to balance immunosuppression (chance of infections) against the need to stabilise the disease perioperatively (stopping disease-modifying drugs can lead to flare up of the disease).

In ankylosing spondylitis patients in addition to the problems discussed above, techniques of spinal or epidural anaesthesia are often challenging. Patients with systemic lupus erythematosus may exhibit a hypercoagulable state along with airway difficulties.

Airway assessment

The ability to intubate the trachea and oxygenate the patient are basic and crucial skills of the anaesthetist. The ease or difficulty in performing airway manoeuvres can be predicted by simple examination findings of full mouth opening (modified Mallampati class), jaw protrusion, neck movement and thyromental distance. The Samssoon and Young modified Mallampati test is performed with the clinician sitting in front of the patient, with the patient's mouth open and tongue protruding (Figure 16.6). The higher the grade, the higher the risk in obtaining and securing an airway (Table 16.4). Look for loose teeth, obvious tumours, scars, infections, obesity, thickness of the neck, etc., which will indicate difficulty in obtaining the airway. When more than one of the above tests is positive, the chances of experiencing difficulty in obtaining and securing the airway become greater.

Table 16.4 Airway assessment (Samssoon and Young modified Mallampati test).

Fauces, pillars, soft palate and uvula seen	Grade 1
Fauces, soft palate with some part of uvula seen	Grade 2
Soft palate seen	Grade 3
Hard palate only seen	Grade 4

Figure 16.6 Normal mouth opening view.

Preoperative assessment in emergency surgery

In urgent or emergency surgery, the principles of preoperative assessment should be the same as in elective surgery, except that the opportunity to optimise the condition is limited by time constraints. Medical assessment and treatments should be started (e.g. according to the Advanced Trauma Life Support (ATLS) guidelines) even if there is no time to complete those before the surgical procedure is started. Some risks may be reduced, but some may persist and whenever possible these need to be explained to the patient (Summary box 16.6).

Summary box 16.6

Preoperative assessment for emergency surgery

- Start: Similar principles to that for elective surgery
- Constraints: Time, facilities available
- Consent: May not be possible in life-saving emergencies
- Organisational efforts: For example, local/national algorithms for treatment of multi-trauma patient

RISK ASSESSMENT AND CONSENT

All life- or limb-threatening complications and all complications with an incidence of 1 per cent or more should be discussed with the patient (Table 16.5). The risk of death doubles with every seven years of adult life lived. The presence of peripheral vascular disease, stroke, heart failure, myocardial infarction or renal failure each independently increases the risk of death by

Table 16.5 Perioperative teams.

Ward, theatre and specialist nursing staff
Anaesthetic and surgical teams
Radiology, pathology involvement
Rehabilitation and social care workers
Specific personnel in individual cases

about 1.5 times the baseline. The risks of the surgical procedure itself are then to be added on separately.

Valid consent implies that it is given voluntarily by a competent and informed person who is not under duress (see LED TO REASON in Table 16.6). In emergency situations or in an unconscious patient, consent may not be obtained and the procedure carried out 'in the best interests of the patient'.

Adults are presumed to have capacity to consent unless there is contrary evidence. For adults who are not deemed competent to give consent, treatment can still proceed in their best interests by filling in an inability to consent form. Those under 16 years who demonstrate the ability to appreciate the risks and benefits fully are deemed competent. This is known as Gillick competence (Summary box 16.7).

Summary box 16.7

Risk assessment and consent

- Risks: Related to the comorbidities, anaesthesia and surgery
- Explain: Advantages, side effects, prognosis
- Language: Simple, use daily life comparisons to explain risks
- Consents: Valid consent is necessary except in life-saving circumstances

ARRANGING THE THEATRE LIST

The date, place and time of operation should be matched with availability of personnel. Appropriate equipment and instruments should be made available. The operating list should be distributed as early as possible to all staff who are involved in making the list run smoothly (Table 16.5).

Prioritise patients, e.g. children and diabetic patients should be placed at the beginning of the list; life- and limb-threatening surgery should take priority; cancer patients need to be treated early.

Table 16.6 Taking a comprehensive consent (acronym LED TO REASON).

L ead in	Introduce yourself and identify the patient
E xplore	How much does the patient know
D iagnosis	Why the operation is being proposed
T reatment	Explain whether the treatment proposed is in accordance with protocols and if not why not
O ptions	Discuss all the options including that of doing nothing, use lay language
R esults	Explain likely outcome in terms of pain, mobility, work, diet and return to normal activities
E ventualities	For example, the possibility of needing to remove the testicle in a hernia operation
A dverse events	Myocardial infarction, stroke and embolus, bleeding and specific damage
S ound mind	Ask if they have understood
O pen question	Check if further clarification is needed
N otes	Document everything discussed and agreed

CHAPTER
17Anaesthesia and
pain relief

LEARNING OBJECTIVES

To gain an understanding of:

- Techniques of anaesthesia and airway maintenance
- Methods of providing pain relief
- Local and regional anaesthesia techniques
- The management of chronic pain and pain from malignant disease

HISTORY

Anaesthesia, as we know it today was first successfully demonstrated by William Morton, a local dentist, at the Massachusetts General Hospital in Boston, USA on October 16, 1846 when he administered ether to Gilbert Abbot for operation on a vascular tumour on his neck. Earlier, Horace Wells had successfully used nitrous oxide in 1844 for painless extraction of teeth.

Simpson at Edinburgh University overcame some of the technical difficulties of ether administration by introducing chloroform. The benefits of anaesthesia were then universally recognised and antagonism by religious leaders was countered when Queen Victoria accepted chloroform from John Snow during the birth of Prince Leopold in 1853.

KEY PRINCIPLES OF ANAESTHESIA

Optimum patient care is dependent on a collaborative approach from anaesthetic and surgical teams. The importance of multi-disciplinary collaboration has been clearly demonstrated by national audits such as the *Confidential Enquiries in Perioperative Deaths (CEPOD)* and *Enquiries into Maternal Deaths UK*. These

audits have led to changes in clinical and non-clinical practice to improve morbidity and mortality.

The use of a set of safety checklists in the operating theatre in the form of the *WHO Surgical Safety Checklist* has shown a reduction in incidence of perioperative untoward events.

The role of the modern anaesthetist has evolved from just being responsible for the patient in the operating suite into a 'perioperative physician' who optimises the patient for surgery, assessing and minimising risk, cares for them during the operation, and then manages both pain and homeostasis in the post-operative period (Table 17.1) (Summary box 17.1).

Summary box 17.1

Ground rules for anaesthesia

- Safe surgery is achieved by close teamwork between surgeon and anaesthetist
- Safety checklists make sure that things are not forgotten
- Risk assessment allows the best strategy to be chosen
- Anaesthetists are extending their care into the pre- and postoperative phase

Table 17.1 Key features of commonly used intravenous anaesthetic agents.

Propofol (di-isopropyl phenol)	Smooth induction, better haemodynamic stability, blunting of autonomic reflexes and ability to use as a continuous infusion
Thiopentone (barbiturate)	Rapid induction, myocardial depression. Reduced metabolic rate and lowering of intracranial pressure is useful in neurosurgical patients, but drop in blood pressure can have detrimental effects
Etomidate (steroid derivative)	Good haemodynamic stability, brief duration of action, but concern over adrenocortical depression
Ketamine (phencyclidine derivative)	Preservation of blood pressure and respiratory reflexes together with excellent analgesia makes it an ideal choice for field anaesthesia. Emergence delirium is associated with administration of ketamine

William Thomas Gren Morton, 1819–1868, a dentist who practised in Boston, MA, USA.

John Collins Warren, 1778–1856, Professor of Anatomy and Surgery, The Harvard Medical School, Boston, MA, USA.

Robert Liston, 1794–1847, surgeon, University College Hospital, London, UK.

Sir James Young Simpson, 1811–1870, Professor of Midwifery, Edinburgh, UK.

Alexandrina Victoria, Queen of the United Kingdom of Great Britain and Ireland, 1837–1901.

John Snow, 1813–1858, a general practitioner of London, UK, who was one of the pioneers of anaesthesia.

Prince Leopold, 1853–1884, who later became Duke of Albany, was the eighth of Queen Victoria's nine children, and her fourth son.

PREPARATION FOR ANAESTHESIA

In cooperation with the anaesthetist, a surgeon's job is to perform a thorough preoperative assessment which recognises medical and anaesthetic risk factors, and facilitates the optimisation of the patient's condition.

A careful preassessment, multidisciplinary approach, standardised care pathway with a carefully chosen anaesthetic and analgesic technique is the cornerstone of 'enhanced recovery programmes', which were introduced recently across the surgical specialities.

GENERAL ANAESTHESIA

General anaesthesia is commonly described as the triad of unconsciousness, analgesia and muscle relaxation (Summary box 17.2).

Summary box 17.2

The general anaesthetic triad

- Amnesia: loss of awareness
- Analgesia: pain relief
- Muscle relaxation

Induction of general anaesthesia is most frequently done by intravenous agents. Propofol has replaced thiopentone as the most widely used induction agent and can be used for maintenance of anaesthesia. Other infrequently used intravenous agents include etomidate and ketamine. Newer agents based on benzodiazepine receptor agonist, etomidate derivatives and fospopofol are still in the experimental stage.

Inhalational induction using agents such as non-pungent sevoflurane is useful in children, needle-phobic adults and those in whom a difficult airway is anticipated. These patients will have a higher risk of developing airway obstruction (Figure 17.1).

Rapid sequence induction (RSI) using a predetermined dose of intravenous anaesthetic agent together with rapidly acting muscle relaxant is used in those with high risk of regurgitation in order to secure the airway quickly. Commonly needed in emergency surgery, it is also a technique of choice in any non-emergency surgery in a patient with delayed emptying of stomach.

Total intravenous anaesthesia (TIVA) is becoming popular following the introduction of propofol and ultra-short acting opioid remifentanyl. The lack of a cumulative effect, better haemodynamic stability, excellent recovery profile and concerns over the environmental effects of inhalational agents have made TIVA an attractive choice. TIVA is routinely used in neurosurgery, in airway laser surgery, during cardiopulmonary bypass and for day-case anaesthesia (Figure 17.2) (Summary box 17.3).

Maintenance of anaesthesia, on the other hand, can be done using continuous infusion of intravenous agent (propofol) or inhaled vapour such as isoflurane, sevoflurane or desflurane.

The use of nitrous oxide is declining despite its analgesic and weak anaesthetic properties due to concerns over postoperative nausea and vomiting. It also increases the size of the air bubble causing adverse effects, for example in eye, ear and abdominal surgery. Finally, it is possibly mutagenic and is a powerful greenhouse gas.

Figure 17.1 Anaesthetic machine.

Figure 17.2 Total intravenous anaesthesia (TIVA) pumps in use.

Summary box 17.3

Special terms in anaesthesia

- Rapid sequence induction (RSI) is a technique that allows the airway to be rapidly secured. It is used when there is a high risk of regurgitation that may lead to pulmonary aspiration
- Total intravenous anaesthesia (TIVA) is becoming increasingly popular

Management of airway during anaesthesia

Loss of muscle tone as a result of general anaesthesia means that the patient can no longer keep their airway open. Therefore, the patients need their airway maintained for them. The use of muscle relaxants will mean that they will also be unable to breathe for themselves and so will require artificial ventilation. Head tilt, chin lift and jaw thrust manoeuvres along with adjuncts such as oropharyngeal airways are used to facilitate bag-mask ventilation, while induction agents exert full effect. Laryngeal mask airway or endotracheal tube is then inserted and the patient is allowed to breathe spontaneously or is ventilated during the procedure.

The addition of a cuff to the endotracheal tube facilitates positive pressure ventilation and protects the lungs from aspiration of regurgitated gastric contents.

- **Laryngeal mask airway (LMA).** Developed by Dr Archie Brain in the UK, the mask with an inflatable cuff is inserted via the mouth and produces a seal around the glottic opening, providing a very reliable means of maintaining the airway. Its placement is less irritating and less traumatic to a patient's airway than endotracheal intubation. The technique can be easily taught to non-anaesthetists and paramedics and can be used as an emergency airway management tool. Several varieties of LMA are available including reinforced, I-gel and an intubating LMA that aids endotracheal intubation (Figure 17.3).
- **Difficult intubation.** Endotracheal intubation is feasible in most patients, but in a certain proportion of patients this may be difficult or impossible; if compounded by inability to ventilate the patient by bag-mask, the consequences can be catastrophic hypoxia. Many devices have been developed to aid intubation if difficulty is anticipated and protocols have been created by specialised societies to deal with such situations. The gold standard for intubation in difficult situations is the use of the fiberoptic intubating bronchoscope, facilitated by topical local anaesthetic in awake patients or using general anaesthesia. The anaesthetist places the endotracheal tube in the trachea by threading the tube over the bronchoscope and so places the tube in the trachea under direct bronchoscopic vision (Figures 17.4, 17.5 and 17.6).

Figure 17.3 The laryngeal mask airway. The laryngeal mask airway (left), I-gel airway (centre) and reinforced laryngeal mask airway (right).

Figure 17.4 The Macintosh laryngoscope with a standard blade (left) and McCoy's modification of the Macintosh blade (right).

Figure 17.5 Endotracheal devices. From left to right: an uncut orotracheal tube; reinforced orotracheal tube; oral version of an RAE (Ring, Adair and Elwyn) preformed tube; nasal version of an RAE preformed tube; tracheostomy tube.

Figure 17.6 Fiberoptic intubating bronchoscope.

Double-lumen tubes and endobronchial tubes are used in procedures such as thoracoscopic, pulmonary and oesophageal surgery to allow collapse of one lung (while ventilating the other) for ease of surgery. Their use is also essential to isolate the healthy lung in pyopneumothorax and in case of bronchopleural fistula.

Ventilating bronchoscope and endobronchial catheters can be used to maintain oxygenation during laryngotracheal surgery or bronchoscopy by using intermittent jets of oxygen (Summary boxes 17.4 and 17.5).

Summary box 17.4

Techniques for maintaining an airway

- Chin lift and jaw thrust: suitable for short term when no aid available
- Guedel airway: holds tongue forward but does not prevent aspiration
- Laryngeal mask: easy insertion, reliable airway, allows ventilation
- Endotracheal intubation: secure and protected airway

Summary box 17.5

Complications of intubation

- Failed intubation
- Accidental bronchial intubation
- Trauma to teeth, pharynx and larynx
- Aspiration of gastric contents during intubation
- Disconnection, blockage, kinking of tube
- Delayed tracheal stenosis

Muscle relaxation and artificial ventilation

Pharmacological blockade of neuromuscular transmission provides relaxation of muscles allowing easy surgical access, but the patient requires artificial ventilation.

Neuromuscular blocking agents are broadly classified into depolarising and non-depolarising groups according to their mode of action.

Suxamethonium is the most commonly used depolarising agent. It binds to the nicotinic acetylcholine receptors resulting in opening of the cation channel leading to depolarisation and rapid relaxation of muscles. Despite its adverse effects, such as hyperkalaemia, muscle pain, anaphylaxis and potentially life-threatening malignant hyperthermia, suxamethonium is still widely used because of its quick onset and short duration of action. These properties are useful where rapid endotracheal intubation is necessary to protect the patient's airway or short duration surgery is performed.

Non-depolarising muscle relaxants act by competitive blockade of postsynaptic receptors at the neuromuscular junction. They provide longer, predictable activity, but require careful monitoring, appropriate timing and reversal of their action by agents, such as neostigmine and sugammadex, at the end of the procedure. A peripheral nerve stimulator is routinely used to monitor the depth of neuromuscular block and also to confirm satisfactory recovery of muscle power prior to extubation (Table 17.2).

Table 17.2 Properties of commonly used muscle relaxants.

Suxamethonium	Quickest onset, very short duration, spontaneous recovery. Ideal for rapid intubation and for short procedures	Muscle pain, hyperkalaemia, prolonged apnoea and life-threatening malignant hyperthermia
Vecuronium	Long-acting, minimal cardiovascular effect and less allergic reaction	Dependent on hepatic metabolism and renal clearance, hence caution if hepatic and renal impairment
Atracurium	Intermediate acting. Non-enzymatic Hoffmann degradation. Suitable in renal and hepatic failure	Histamine release and allergic reactions
Rocuronium	Rapid onset, intermediate action. Suitable for rapid intubation. Rapid reversal possible using Sugammadex	Allergic reaction. Excreted unchanged via bile and urine

Ventilation during anaesthesia

Mechanical ventilation is required when the patient's spontaneous ventilation is inadequate or when the patient is not breathing because of the effects of the anaesthetic, analgesic agents or muscle relaxants.

In volume control ventilation, a preset volume is delivered by the machine irrespective of the airway pressure. The pressure generated will be in part dependent on the resistance and compliance of the airway. In laparoscopic surgery requiring the Trendelenburg position (the patient is positioned head down), and in morbidly obese patients and those with lung disease, this may result in excessive pressures being developed, which may lead to barotrauma (pneumothorax).

In pressure control mode, the ventilator generates flow until a preset pressure is reached. The actual tidal volume delivered is variable and depends on airway resistance, intra-abdominal pressure and the degree of relaxation.

Positive end expiratory pressure (PEEP) is often applied to help maintain functional residual capacity (FRC). This avoids lung collapse by opening collapsed alveoli, and maintains a greater area of gas exchange so reducing vascular shunting (Summary box 17.6).

Summary box 17.6

Intermittent positive pressure ventilation

- Volume controlled which ensures adequate gas entry, but risks high pressure damage
- Pressure controlled which avoids high pressure damage but risks inadequate ventilation
- Positive end expiratory pressure (PEEP) reduces alveolar collapse and reduces vascular shunting so improving perfusion

Monitoring and care during anaesthesia

A minimum basic monitoring of cardiovascular parameters is required during surgery. This includes:

- Vascular
 - electrocardiogram (ECG)
 - blood pressure
- Adequacy of ventilation:
 - inspired oxygen concentration
 - oxygen saturation by pulse oximetry
 - end tidal carbon dioxide concentration.

Monitors of temperature, ventilation parameters and delivery of anaesthetic agents are also routinely used, while measurement of urine output and central venous pressure are recommended for major surgery.

Anaesthesia for day case surgery

This is discussed in Chapter 22.

LOCAL ANAESTHESIA

Local anaesthetic drugs may be used to provide anaesthesia and analgesia as a sole agent or as adjuncts to general anaesthesia. Available techniques include topical anaesthesia, local infiltration, regional nerve blocks and central neuroaxial blocks (spinal and epidural anaesthesia) (Table 17.3).

Local anaesthesia techniques can lead to complications that may be local like infection or haematoma, or systemic due to overdose or accidental intravascular injection. The systemic effects of local anaesthetic agents are dose dependent and manifest as cardiovascular (cardiac arrhythmia, cardiac arrest) or neurological (depressed consciousness, convulsions). Prilocaine overdose causes methaemoglobinaemia while bupivacaine overdose causes treatment-resistant ventricular arrhythmia and cardiac arrest.

The addition of adrenaline to local anaesthetic solutions hastens onset, prolongs duration of action and permits a higher upper dose limit. The use of adrenaline is contraindicated in patients with cardiovascular disease, those taking tricyclic and monoamine oxidase inhibitors, and in end-arterial locations.

Appropriately skilled personnel, resuscitation equipment and oxygen should always be available with local anaesthetic use because of the potential risks of life-threatening complications.

Regional anaesthesia

Regional anaesthesia involves central neuroaxial or peripheral nerve or plexus blocks. It has a clear advantage where general anaesthesia carries a higher risk of morbidity and mortality, such as in patients with debilitating respiratory and cardiovascular disease and obstetric cases. It also provides excellent pain relief

in the postoperative period reducing the need for analgesics, such as opioids.

As with general anaesthesia obtaining venous access, monitoring vital parameters should be performed during regional anaesthesia.

Localising nerves using anatomical landmarks and eliciting paraesthesia alone carries a high risk of nerve damage, intravascular injection, and has a lower success rate. The use of nerve stimulators to localise nerves improves success rate and reduces risks. Ultrasound-guided regional anaesthesia allows the visualisation of nerves and the spread of local anaesthetics enabling use of a smaller dose of local anaesthetic agents with improved success rates and safety (Summary box 17.7).

Summary box 17.7

Types of anaesthesia

- General anaesthesia may be more acceptable to the patient
- Regional anaesthesia has major advantages in obstetrics and patients with respiratory compromise
- Local blocks have been transformed by nerve stimulators and ultrasound guidance
- All require full resuscitation and monitoring equipment to be available

Common local anaesthesia techniques

Topical anaesthesia

- **EMLA (eutectic mixture of local anesthetics).** This is a mixture of lignocaine and prilocaine for application to the skin for venepuncture in children.
- **Cocaine.** It may be called Mofatt's solution and used in nasal surgery for anaesthesia and vasoconstriction.
- **Lignocaine 4%.** Spray to anaesthetise the airway during awake fiberoptic intubation.

Nerve blocks

- Interscalene block for shoulder surgery produces excellent postoperative analgesia. Complications include phrenic nerve block, Horner's syndrome, as well as accidental intravascular and spinal injection.
- Axillary brachial plexus block can be used as the sole anaesthetic technique for upper limb surgery (Figure 17.7).
- Femoral and sciatic nerve blocks are often used for anaesthesia and analgesia for lower limb surgery.

Transversusabdominis plane block

The transversusabdominis plane (TAP) block is growing rapidly in popularity. The technique has been shown to provide

Table 17.3 The common local anaesthetic drugs.

Name	Maximum dose	Comments
Lignocaine	3 mg/kg (7 mg/kg with adrenaline)	Early onset, short acting, good sensory block
Bupivacaine	2 mg/kg	Long-lasting, more cardiotoxic, must never be used intravenously
Prilocaine	6 mg/kg (9 mg/kg with adrenaline)	Least systemic toxicity, causes methaemoglobinaemia
Ropivacaine	3–4 mg/kg (225 mg)	Less cardiotoxic, greater sensory–motor separation
Levobupivacaine	2 mg/kg	Isomer of bupivacaine with less cardiotoxic properties

Figure 17.7 (a,b) Ultrasonic scans of brachial plexus block.

effective analgesia after a wide range of abdominal surgery. The T6–L1 segmental nerves enter the Triangle of Petit just medial to the anterior axillary line. Injection of local anaesthetic into the fascial plane between the internal oblique and transversus abdominis muscles allows a block of all these nerves, and excellent anaesthesia of the anterior abdominal wall (Figure 17.8).

Intravenous regional anaesthesia (Bier's block)

Bier's block produces excellent anaesthesia for short surgery, particularly for the upper limb (e.g. carpal tunnel release). Exsanguination using an Esmarch bandage, inflation of proximal cuff of the double tourniquet is followed by intravenous injection of prilocaine into the vein on the back of the hand that is being operated on. After 5–10 minutes, the distal cuff of the tourniquet is inflated and then the proximal one deflated. Even if surgery is finished, the tourniquet should be left inflated until the local anaesthetic has bound to tissues (20 minutes) so that release of local anaesthetic into the systemic circulation does not occur. Lignocaine can be used with caution (consider safe dose and time of tourniquet inflation), but bupivacaine should never be used for Bier's block.

Spinal anaesthesia

Spinal anaesthesia alone, in combination with general anaesthesia or sedation is used extensively for lower limb, obstetric and pelvic surgery. Injection of a 'single shot' local anaesthetic agent intrathecally produces intense and rapid block for surgery. Addition of opioids provides prolonged postoperative analgesia, but carries the risk of late respiratory depression.

Autonomic sympathetic blockade produces hypotension, particularly if the level of block is above T10. Caution is needed in patients with hypovolaemia and cardiovascular disease.

The incidence of dural puncture headache can be minimised

Figure 17.8 (a,b) Ultrasonic scans of lateral abdominal wall and the spread of local anaesthetics.

by limiting the number of punctures and use of fine bore pencil tip needles designed to split rather than cut the dura.

Epidural anaesthesia

Epidural anaesthesia is slower in onset than spinal, but has the advantage of prolonged analgesia by multiple dosing or continuous infusion through a catheter placed in the epidural space. Being slower in onset, the resulting hypotension from sympathetic blockade can be better controlled and can reduce blood loss.

Continuous infusion (with a patient-controlled bolus) of weak local anaesthetic combined with opioids (such as fentanyl) is routinely used for postoperative analgesia. Placement of an epidural catheter in the high thoracic region provides excellent analgesia for a wide variety of upper abdominal and thoracic surgical operations enabling early mobilisation and reducing respiratory complications.

Epidural anaesthesia is technically more difficult than spinal anaesthesia with a higher failure rate and carries the risk of nerve damage, spinal injuries, accidental spinal injection of large volume of local anaesthetics and risk of infection and epidural haematoma (Figures 17.9 and 17.10) (Summary box 17.8).

Summary box 17.8

Local anaesthetics

- EMLA cream for children needing injections
- Regional and nerve blocks for limb surgery
- Spinal anaesthesia offers quick onset and short duration of anaesthesia
- Epidurals are more difficult, but can then be topped up postoperatively and used as continuous infusion

Edward Boyce Tuohy, 1908–1959, Professor of Anaesthesiology, Georgetown Medical Center, Washington DC (1947–1952) and later at the University of Southern California Medical School, Los Angeles, CA, USA.

August Karl Gustav Bier, 1861–1949, Professor of Surgery, Bonn (1903–1907) and Berlin, Germany (1907–1932).

Ralph J Huber, 1890–1953, a dentist in Seattle, WA, USA.

Ralph Douglas Kenneth Reye, 1912–1977, Director of Pathology, The Royal Alexandra Hospital for Children, Sydney, NSW, Australia, described this syndrome in 1963.

Figure 17.9 Patient positioned for epidural/spinal anaesthesia.

Figure 17.10 Equipment for epidural/spinal anaesthesia.

Chronic pain management

In surgical practice, the patient with chronic pain may present for treatment of the cause (e.g. pancreatitis, malignancy) or concomitant benign pathology. Acute pain after surgery may progress to chronic pain and is believed to be due to inadequate treatment of acute pain itself.

Chronic pain may be of several types:

- **Nociceptive pain** may result from musculoskeletal disorders or cancer activating cutaneous nociceptors (pain receptors). Prolonged ischaemic or inflammatory processes result in sensitisation of peripheral nociceptors and altered activity in the central nervous system leading to exaggerated responses in the dorsal horn of the spinal cord. The widened area of hyperalgesia and increased sensitivity (allodynia) has been attributed to the increased transmission in the central nervous system.

- **Neuropathic (or neurogenic) pain** is dysfunction in peripheral or central nerves (excluding the 'physiological' pain due to noxious stimulation of the nerve terminals). It is classically of a 'burning', 'shooting' or 'stabbing' type and may be associated with allodynia, numbness and diminished thermal sensation. It is poorly responsive to opioids. Examples include trigeminal neuralgia, postherpetic and diabetic neuropathy. Monoaminergic, tricyclic inhibitors and anticonvulsant drugs are the mainstay of treatment.
- **Psychogenic pain** is associated with depressive illness; chronic pain and the illness may exacerbate each other (Summary box 17.9).

Summary box 17.9

Types of pain

- Nociceptive pain arises from inflammation and ischaemia
- Neuropathic pain arises from a dysfunction in the central nervous system
- Psychogenic pain is modified by the mental state of the patient

Chronic pain control in benign disease

Surgical patients may have persistent pain from a variety of disorders including chronic inflammatory disease, recurrent infection, degenerative bone or joint disease, nerve injury and sympathetic dystrophy. This may result from persistent excitation of the nociceptive pathways causing spontaneous firing of pain signals at N-methyl-D-aspartate receptors in the ascending pathways. This pain does not respond to opiates or neuroablative surgery.

Amputation of limbs may result in phantom limb pain, the likelihood is increased if the limb was painful before surgery. Continuous regional local anaesthetic blockade (epidural or brachial plexus) established before operation and continued postoperatively for a few days, is believed to effectively reduce the risk of phantom limb pain (Summary box 17.10).

- **Local anaesthetic and steroid injections** can be effective around an inflamed nerve and they reduce the cycle of constant pain transmission with consequent muscle spasm. Epidural injections are used for the pain of nerve root irritation associated with minor disc prolapse along with active physiotherapy to promote mobility.
- **Nerve stimulation procedures** such as acupuncture, transcutaneous nerve stimulation, and spinal cord stimulators increase endorphin production in the central nervous system. Nerve decompression craniotomy rather than percutaneous coagulation of the ganglion is now performed for trigeminal neuralgia.

Summary box 17.10

Pain control in benign disease

- Bring pain under control before amputation to avoid phantom pain
- Local anaesthetic and steroid injected around a nerve may reduce muscle spasm
- Transcutaneous nerve stimulators (TNS) modify pain by increasing endorphin production
- Trigeminal neuralgia responds to decompression of the nerve

Drugs in chronic non-malignant pain

Paracetamol and the non-steroidal anti-inflammatory drugs (NSAID) are the mainstay of musculoskeletal pain treatment. The tricyclic antidepressant drugs and anticonvulsant agents are often useful for the pain of nerve injury, although side effects can prove troublesome and reduce compliance. Both pregabalin and gabapentin reduce spontaneous neuronal activity and are now used for managing the neuropathic chronic pain. In more severe and debilitating non-malignant chronic pain, opioid analgesic drugs are used in slow release oral preparations of morphine and oxycodone, and transcutaneous patches delivering fentanyl and buprenorphine. Combinations of drugs often prove useful to achieve the optimum of efficacy with minimal side effects.

Treatment of pain dependent on sympathetic nervous system activity

Even minor trauma and surgery (often of a limb) can provoke chronic burning pain, allodynia, trophic changes and resultant disuse due to excessive sympathetic adrenergic activity inducing vasoconstriction and abnormal nociceptive transmission.

Management may include a test response to systemic α -adrenergic blockade using intravenous phentolamine and/or local anaesthetic injection of stellate ganglion or lumbar sympathetic chain. Percutaneous chemical lumbar sympathectomy with phenol/local anaesthetic is used for relief of rest pain in advanced ischaemic disease of the legs. It has an added advantage as it assists in the healing of ischaemic ulcers by improving peripheral blood flow.

Pain control in malignant disease

Pain is a common symptom associated with cancer, more so during the advanced stages. In intractable pain, the underlying principle of treatment is to encourage independence of the patient and an active life in spite of the symptom. The World Health Organization's booklet advises use of a 'pain step ladder':

- First step. **Simple analgesics:** aspirin, paracetamol, non-steroidal anti-inflammatory agents, tricyclic drugs or anticonvulsant drugs.
- Second step. **Intermediate strength opioids:** codeine, tramadol or dextropropoxyphene.
- Third step. **Strong opioids:** morphine (pethidine has now been withdrawn).

Oral opiate analgesia is necessary when the less powerful analgesic agents no longer control pain on movement, or enable the patient to sleep. Fear that the patient may develop an addiction to opiates is usually not justified in malignant disease. It is also important to distinguish between the addiction and dependence; the former being a psychosocial phenomenon while the latter is a pure physiological response to a given drug. Some patients experience 'breakthrough pain' (acute, excruciating and incapacitating), which occurs either spontaneously or in relation to a specific predictable or unpredictable trigger, experienced by patients who have relatively stable and adequately controlled background pain.

Oral morphine, often used for chronic pain, can be prescribed in short-acting liquid or tablet form and should be administered regularly every 4 hours until an adequate dose of drug has been titrated to control the pain over 24 hours. Once this is established, the daily dose can be divided into two separate

administrations of enteric-coated, slow-release morphine tablets (MST morphine) every 12 hours. Additional short-acting opioids (morphine/fentanyl) can then be used to cover episodes of breakthrough pain. Nausea treated using anti-emetic agents does not usually persist, but constipation is a frequent and persistent complication requiring regular prevention with laxatives.

Infusion of subcutaneous, intravenous, intrathecal or epidural opiate drugs

The infusion of opiates is necessary if a patient is unable to take oral drugs. Subcutaneous infusion of diamorphine is simple and effective to administer. Epidural infusions of diamorphine with an external pump can be used on mobile patients. Intrathecal infusions with pumps programmed by external computer are used, however, there is a possibility of developing infection with catastrophic effects. Intravenous narcotic agents may be reserved for acute crises, such as pathological fractures.

Neurolytic techniques in cancer pain

These should only be used if the life expectancy is limited and the diagnosis is certain. The useful procedures are:

- Subcostal phenol injection for a rib metastasis.
- Coeliac plexus neurolytic block with alcohol for pain of pancreatic, gastric or hepatic cancer.
- Intrathecal neurolytic injection of hyperbaric phenol.
- Percutaneous anterolateral cordotomy divides the spinothalamic ascending pain pathway. It is a highly effective technique in experienced hands, selectively eliminating pain and temperature sensation in a specific limited area.

Alternative strategies include:

- The development of anti-pituitary hormone drugs, such as tamoxifen and cyproterone, enables effective pharmacological therapy for the pain of widespread metastases instead of pituitary ablation surgery.
- Palliative radiotherapy can be most beneficial for the relief of pain in metastatic disease.
- Adjuvant drugs, such as corticosteroids to reduce cerebral oedema or inflammation around a tumour, may be useful in symptom control. Tricyclic antidepressants, anticonvulsants and flecainide are also used to reduce the pain of nerve injury (Summary box 17.11).

In the management of chronic pain, a multidisciplinary approach by a team of medical and nursing staff working with psychologists, physiotherapists and occupational therapists can often achieve much more benefit than the use of powerful drugs. Pain management programmes lay out a logical structure for this.

Summary box 17.11

Options for controlling severe pain in malignant disease

- Oral morphine using slow-release, enteric-coated tablets
- Slow infusion of opiates subcutaneously, by epidural, or intrathecally
- Neurolysis for patients with limited life expectancy
- Palliative hormone, radiotherapy, or steroids control pain from swelling

CHAPTER 18

Care in the operating room

LEARNING OBJECTIVES

To understand:

- How to prepare a patient for theatre
- The importance of the World Health Organization checklist and its components
- How to reduce intraoperative risks of positioning, venous thromboembolism, infection and hypothermia, by using appropriate monitoring and equipment.
- The operating theatre environment and how to behave in it, including scrubbing up, the role of the assistant and how to write an operation note.

'First do no harm.'

Hippocrates

PREOPERATIVE PREPARATION IMMEDIATELY BEFORE SURGERY

Patient preparation

Both the operating surgeon and the anaesthetist should see the patient prior to surgery. The patient's identity and the proposed surgery should be confirmed. After explaining the risks and benefits to the patient, valid consent for surgery should be obtained. There should be an opportunity for questions, and the patient should have adequate time to make their decision (see LED TO REASON Table 16.6). Any changes in the patient's condition since listing for surgery should be noted, and a check made for any contraindications to elective surgery, e.g. intercurrent illness or remote site infection. In procedures that may cause neurovascular complications, the preoperative neurovascular status should be assessed and documented. Check that all relevant results and imaging are available, and that the side or area to be operated on is marked with an arrow at or near to the incision site.

Theatre team preparation

Preoperative planning should cover all aspects of the surgical process. Close communication and coordination between preoperative departments and operating theatres allows timely preparation and improves efficiency and safety in the operating theatre.

Every hospital will have a policy for booking and scheduling of elective and emergency theatre cases.

The theatre list should have a header with the date, time and details of the theatre, surgeon and anaesthetist. For each opera-

tion, the patient's name and hospital number, preoperative ward, operation title and site of surgery should be recorded. Additional information may include the need for specialised equipment or implants, instrument sets, use of a specific operating table, patient positioning, availability of blood products and need for postoperative higher dependency care.

Up-to-date information about the operating lists must be available to all personnel including patients, ward staff, porters, theatre and recovery staff. Lists should be scheduled to meet the needs of the patient, theatre team and staff in other disciplines. For example, infectious patients should be listed last to avoid delays from theatre contamination. Children and diabetic patients will need to go first.

Support services, e.g. radiology for intraoperative imaging, haematology for blood products, cell salvage and pathology for frozen sections, should also be informed and be available. A good operation list contains all the relevant information and is distributed on time to everyone involved so that there are 'no surprises' for anyone (Summary box 18.1).

Summary box 18.1

Before theatre

- Patient must be seen by anaesthetist and operating surgeon preoperatively
- Communicate early with theatre team regarding specific requirements
- Arrange theatre list appropriately for the case-mix and resources available

IN THEATRE

Surgical safety checklist

In 2008, the World Health Organization (WHO) published guidelines of recommended practices to reduce the rate of preventable surgical complications and death worldwide. A core set of checks have been incorporated into the WHO surgical safety checklist, which should be completed for every patient undergoing a surgical procedure. In the UK, a five-step process is used to improve theatre team communication and to verify and check essential care interventions (Summary box 18.2).

Summary box 18.2

WHO Surgical Safety Checklist: UK process

- Step 1: Prelist briefing
- Step 2: Sign in
- Step 3: Time out
- Step 4: Sign out
- Step 5: Postlist debriefing

Prelist briefing

A short meeting before the start of the operating list provides an opportunity for the theatre team to introduce themselves, share information about potential safety problems and highlight concerns about specific patients to ensure smooth running of the list. For example, patient issues such as positioning, allergies and imaging, anticipated surgical complications, last minute list order changes and the need for antibiotics and thromboembolism prophylaxis may be discussed at this time.

Sign in

The sign in checklist should be read out prior to induction of anaesthesia:

- Has the patient confirmed their identity, site of surgery, procedure and consent?
- Is the surgical site marked?
- Is the anaesthesia machine and medication check complete?
- Does the patient have a known allergy?
- Does the patient have a difficult airway risk or risk of aspiration?
- Does the patient have a risk of >500 mL blood loss (7 mL/kg in children) and if yes, is adequate intravenous access and fluid/blood replacement planned?

Other preoperative checks may vary between institutions, but include ensuring removal of dentures and jewellery, and confirming any implanted metalwork.

Antibiotics

To prevent surgical site infection, patients should receive appropriate antibiotics, using local guidelines, less than an hour before surgical incision. Antibiotic prophylaxis should be given to patients before clean surgery involving insertion of a prosthesis or implant, clean-contaminated surgery or contaminated surgery. Antibiotic prophylaxis should not be used routinely for clean, non-prosthetic surgery. Prophylactic antibiotics should be discontinued within 24 hours of surgery.

Venous thromboembolism

All patients should be risk-assessed preoperatively for venous thromboembolism (VTE). Patients should not be allowed to become dehydrated perioperatively. In theatre, mechanical and pharmacological VTE prophylaxis can be used.

Mechanical methods include:

- anti-embolism graduated compression stockings;
- foot impulse devices;
- intermittent pneumatic compression devices.

The choice of pharmacological VTE agents depends on local policies and individual patient factors, including comorbidities (such as renal failure).

Regional anaesthesia (spinal or epidural) carries a lower risk of VTE than general anaesthesia. If used, plan the timing of pharmacological VTE prophylaxis to minimise the risk of spinal haematoma.

Monitoring

The most important 'monitor' is the presence of a trained, dedicated individual to observe the patient throughout anaesthesia. However, minimum monitoring standards apply in several countries worldwide and their guidance should be followed.

Operating theatre environment

Ventilation

The aim of the air flow system is to prevent airborne microorganisms entering the surgical wound. After filtration, air is introduced at ceiling height and exhausted near the floor with at least 20 air changes per hour. The operating theatre is maintained at positive pressure relative to surroundings. Keeping doors closed and limiting the movement of personnel in and out of theatre will reduce the risk of surgical site infection.

Laminar air flow provides 100–300 air changes per hour and is used in some centres for surgery involving implants, e.g. joint replacements, to avoid airborne infection.

Humidity and temperature

Theatre temperature should be acceptable for the patient and theatre staff. Ideal working temperatures for surgeons are 19–20°C, but patients may develop hypothermia below 21°C. Temperatures of 20–24°C are acceptable with a relative humidity of 50–60 per cent to protect against electrostatic charges.

Patient transfer and positioning

Both transfer and positioning should be performed carefully under the supervision of the anaesthetist and surgeon. These precautions are essential under general anaesthesia as the patient will be immobile and unable to communicate problems; the patient receiving local or regional anaesthesia should also feel comfortable.

Transfer

Patient transfer is coordinated by the anaesthetist, who protects airway devices and other connections during the move. A variety of manual handling aids are used (sliding boards and low-friction sliding sheets) to reduce risks to staff and patient; universal precautions should be maintained by everyone (Figure 18.1).

Figure 18.1 Patient transfer. Enough personnel are available to undertake the transfer. The anaesthetist supervises and protects the head, neck and airway. The patient is rolled and a sliding board (arrow) is placed under the patient and undersheet or canvas, which will allow the patient to slide across to the bed in a controlled fashion. Care is being taken by all of the team members to protect the whole patient.

Positioning

The plan for intraoperative positioning should be communicated to the entire team as it may require specific accessories, such as arm supports, to be available; anaesthetic management may also be affected. Stability of the patient on the table should be ensured using straps and/or solid supports, particularly where anything other than supine positioning is anticipated.

Pressure and stretch injuries resulting from poor positioning are common. High-risk groups include the elderly, the cachectic or the obese. High-risk areas should be checked and padded prior to starting surgery. During lengthy operations, movement of non-involved limbs may be necessary to relieve pressure (Summary box 18.3).

Summary box 18.3

Pressure areas which must be given special consideration

- The skin over bony prominences
- Nerves in superficial courses, e.g. common peroneal nerve (take care with placement of the calves in leg supports)
- Nerves at risk of stretch injury, e.g. brachial plexus (head should be neutral where possible)
- Areas at risk of developing a compartment syndrome
- Eye protection: eyes should be protected from direct pressure (particularly in the prone position), corneal abrasion and splash injuries. Ointment, or eye closure with tape and/or eye pads may be used

In addition, in order to avoid electrical injury, no part of the patient should be in contact with any metal other than the diathermy plate. If radiological imaging is to be used intraoperatively, the patient could be protected with lead shielding and a radiolucent table used.

Finally, the awake patient should be comfortable. A pillow under the knees often relieves the aching low back pain associated with lying supine.

Equipment

Following the induction of anaesthesia, any remaining equipment should be set up, including diathermy, tourniquet and urethral catheterisation, if indicated.

Diathermy

If monopolar diathermy is to be used, the diathermy dispersal electrode must be applied to an appropriate site, which should be:

- clean and dry, free of hair;
- situated over well-perfused muscle mass, avoiding bony prominences, scar tissue, areas distal to tourniquets and implanted metalwork;
- as close to the operative site as feasible;
- checked at the end of surgery for injury.

The patient should not be in contact with any earthed metal appliance. Special consideration must be given to the risks of monopolar diathermy if the patient has implanted devices which may be affected by the current (including pacemakers, implantable defibrillators, cochlear implants and spinal cord stimulators).

Tourniquets

A tourniquet may be used to improve visibility at surgery and to reduce blood loss (Figure 18.2).

The complications of using a tourniquet include neurovascular compression and skin injury due to direct compression, chemical burns from the liberal application of skin preparation fluid which then leaks under the tourniquet, and distal ischaemic/reperfusion injury (Summary box 18.4).

Summary box 18.4

Application of tourniquet

- Appropriate size should be selected
- Apply as proximally as possible
- Apply padding to site without creases
- Apply tightly enough to avoid slippage, but not so tightly as to impede exsanguination
- Exsanguinate the limb prior to inflating the tourniquet using elevation, an Esmarch bandage or a roll cylinder
- When the tourniquet is inflated, the time must be noted
- When the tourniquet is removed, the site should be inspected for damage and the limb for return of circulation. This should be recorded in the notes (with the time)

The precautions which should be taken to avoid these injuries are:

- tourniquet use to be avoided in high-risk patients (including those with sickle cell disease and peripheral vascular disease);
- padding to be used under the tourniquet and tape to prevent fluid leaking underneath it;

Johann Friedrich August von Esmarch, 1823–1965, Professor of Clinical Surgery, Kiel, Germany, devised this type of bandage while working as a military surgeon during the Franco-Prussian war (1870–1871) and described its use in 1873.

Figure 18.2 Tourniquet and tourniquet dressing. (a) Poor placement, too low – interfering with operative field. (b) Optimal placement of the tourniquet using a single-use tourniquet cover, which protects the skin under the tourniquet and has an adhesive strip to prevent ingress of preparation solution (arrow). This tourniquet is less likely to slip and provides a much larger skin preparation field, important as the patient is undergoing knee surgery. (c) Rhys-Davies exsanguinator.

- minimum cuff pressures required for adequate operating conditions to be used: the standard is to set the pressure a constant amount above systolic pressure, 100 mmHg for the upper limb and 150 mmHg for the lower limb;
- use of a tourniquet clock: the surgeon should be informed when 1 hour of 'tourniquet time' has elapsed. It may be appropriate at this point to consider letting the tourniquet down for a short period before reinflating, if more than a few minutes' extra tourniquet time is required. Total tourniquet time should not exceed 1.5 hours.

'Time out'

This must be performed immediately before the surgical procedure starts: it includes team introductions, verbal confirmation of the patient's identity, operative site and procedure to be performed, as well as discussion of anticipated critical events by the surgeon, anaesthetist and nursing team. Confirmation of antibiotic prophylaxis and review of essential imaging (if required) is carried out at this stage.

Specific additional checks including the areas outlined below may be included according to local adaptations of the checklist.

Temperature control

Patients undergoing anaesthesia and surgery lose heat rapidly from radiation to the environment, latent heat of evaporation from exposed wet organs in body cavities or from cleaning fluids applied to the body surface, exposure to cold intravenous fluids and anaesthetic gases. The patient's ability to compensate for these losses is also impaired (reduced metabolic heat production, limited vasoconstriction and the loss of behavioural responses).

The measures which will limit the development of intra-operative hypothermia include the use of forced air warming blankets, warmed intravenous and irrigation fluids, increasing the operating room ambient temperature and minimising exposure of the patient.

Hair removal

This may be necessary over the operative field to facilitate exposure (for incision, suturing and dressing application) or the diathermy plate site (to maximise plate contact with skin). Surgical site infections may be reduced if hair is clipped rather than shaved; there is a lack of evidence to determine whether the timing or location of hair removal affects the incidence of wound infection.

Glycaemic control

The blood glucose needs careful monitoring and controlling in the diabetic patient. Hyperglycaemia perioperatively may increase the incidence of postoperative wound infection. If unrecognised, hypoglycaemia may lead to seizures and death.

Infection control

Asepsis and universal precautions

Cross-infection between patients or between staff member and patient (in either direction) is potentially disastrous and every effort must be made to minimise this risk. In addition to some of the specific areas considered below, universal precautions should be taken in every case involving exposure to body fluids. These include the following:

- protective non-porous gloves, eyewear, mask, apron for staff;

- safe sharps handling techniques and adequate provision of sharps bins;
- staff vaccination for hepatitis B;
- staff with infected wounds or active dermatitis should not work in theatre.

In particular, surgeons handling sharp instruments are responsible for placing them in a safe container (bowl or tray) for transfer, one at a time.

Scrubbing up

The risk of transfer of microbes between staff and patients is minimised by meticulous 'scrubbing up' (washing hands and arms and putting on gown and gloves) (Figures 18.3 and 18.4) (Summary box 18.5).

Figure 18.3 (a,b) Scrubbing up.

Figure 18.4 Gloving techniques. (a) The initial gloving occurs with the hands covered by the gown. The first glove is then placed on to the palmar surface and pulled into position. (b) The double gloving technique, with minimal touch technique. (c) The closed two-person gloving technique; the glove being held open by one person for the second to insert their hand into the glove.

Summary box 18.5**Scrubbing up**

- Hat, mask and eye protection should be worn and jewellery should be removed prior to scrubbing
- Nails and deep skin creases are cleaned for 1–2 minutes using a brush
- Hands and forearms are washed systematically three times, the hands being held above the level of the elbows throughout
- Hands and arms are dried from distal to proximal using a sterile towel
- The folded gown is lifted away from the trolley and allowed to unfold (inside facing the wearer), while the top is held
- Arms are inserted into the armholes simultaneously, hands remaining inside the gown until gloves are donned: the gown is secured by an unscrubbed staff member
- Gloves are put on using a one- or two-person technique: from this point on, hands remain above waist level at all times.

Standard scrub solutions include:

- 2 per cent chlorhexidine (effective for more than 4 hours, potent against Gram-positive and -negative organisms, some viruses, less effective against the tubercle bacillus);
- 7.5 per cent povidone-iodine (duration of effect shorter, highly bactericidal, fungicidal and viricidal; some effect against spores and good anti-tubercle effect);
- alcohols (highly effective against all but spores and inexpensive).

Allergic reactions are recognised to both chlorhexidine and iodine solutions.

Movement in theatre

Scrubbed personnel should:

- keep their hands and arms on the operating table where possible;
- keep their hands away from their faces;
- touch only sterile items or areas;
- watch the sterile fields to avoid contamination;
- not lean over unsterile fields;
- pass each other back-to-back or front-to-front.

Unscrubbed personnel should:

- touch only unsterile items or areas;
- face and observe a sterile area when passing it to be sure that they do not touch it;
- avoid walking between the patient and trays;
- minimise activity near the sterile field.

Instrument trays are prepared by the scrub nurse; supplies are brought to the sterile team members by the non-sterile circulating nurse who opens the outside wrappers and passes the item to the scrub nurse.

Prepping and draping the patient

'Pre-prep' may be indicated where there is visible debris to be removed; it consists of washing the skin with soapy disinfectant, then water or saline, then surgical disinfectant (Figure 18.5).

Patients undergoing elective surgery may instead shower on the day of surgery with a soapy disinfectant.

Skin preparation should include the surgical site and a wide area around it, starting from the incision site and working away from it. Contaminated areas (groin, perineum, axilla) should be covered last. Two coats are usually used and the solutions are similar to those used for scrubbing up (see above). Care should be taken to avoid using excessive amounts of prep solution. This leads to pooling which can cause a chemical burn or ignite in the presence of a spark.

Figure 18.5 Prepping (skin preparation) and draping. Application of skin disinfectant solution to skin. Note that this is the second coat being applied to the posterior aspect of the leg. The leg holder is standing away from the scrub nurse and should be gloved. For this operation, the foot is not being prepped.

Draping aims to create a protective zone around the operative site to avoid contamination of items used for the procedure (Figure 18.6). Both disposable and reusable drapes are suitable, and should be handled only by scrubbed personnel. They should be sited to allow full access to the incision (or any possible extension). Once in place, they should not be disturbed. Skin immediately around the incision site may also be covered with a self-adhesive transparent drape. Diathermy and suction equipment are attached to the drape.

Role of the assistant

Surgical assistants are frequently surgeons in training. They are therefore in theatre to help the senior surgeon and to learn as much as possible (Summary box 18.6).

- **Preparation.** Assistants should review the anatomy and the operation before surgery so that they can anticipate and understand the actions of the senior surgeon. They should start scrubbing first, having checked that the patient is ready for theatre.
- **Training.** Trainees should write important steps of proposed operation in brief on a board in the operating theatre.
- **At surgery.** The assistant should try to provide the surgeon with the best access possible by placing and holding retractors and showing the surgeon the field where they are working.

Figure 18.6 (a) A waterproof underdrape is applied with adhesive edges. A sterile waterproof stockingette is about to be applied by the scrub nurse, initially on to the forefoot with the unscrubbed assistant supporting the heel. The unsterile assistant will then move away carefully from the operating table. All of these drapes are disposable. (b) The stockingettes applied. (c) The final drapes are placed over the stockingettes, the operation sites are covered with clear adhesive and a sterile bandage is used to secure the stockingettes. Some surgeons will prep the feet entirely before draping. Note also the hand position of the surgeon.

Instruments and retractors should always be asked for by name.

- **After surgery.** The assistant should help transfer the patient safely off the table and may write the operative note. They should keep a log of all operations attended and what they have learnt from each case.

Summary box 18.6

In theatre

- The WHO checklist is a universal tool to improve patient safety and should be completed for every patient coming to theatre
- Risks to the patient are minimised by appropriate antibiotic and venous thromboembolism (VTE) prophylaxis, monitoring, careful positioning, temperature, glycaemic and infection control
- The operating theatre environment should be optimised with regard to lighting, ventilation, humidity and temperature
- Additional equipment, such as diathermy and tourniquets, should be used while recognising their potential complications
- Theatre etiquette including scrubbing, prepping and draping and personnel movement is designed to minimise cross-infection

POSTOPERATIVE CARE

'Sign out'

Before any personnel leave theatre, the WHO 'sign out' checks should be completed. These include checking that the procedure has been recorded, that instrument and swab counts are correct, that there have been no equipment problems requiring further action and the key concerns for recovery recorded for the staff taking over care of the patient (Summary box 18.7).

Summary box 18.7

Postoperative care

- The 'sign out' process and postlist briefing complete the WHO checklist
- The operation note should be completed at the time of surgery and contain full patient, personnel and operative information
- Clear postoperative instructions are vital

Writing the operation note

The following information should be included:

- Patient details (name, date of birth, hospital number, address, ward)
- Date and start/finish times of the operation
- Location of the operation
- Name of the operation
- Surgeon, assistant and anaesthetist
- Anaesthetic type
- Patient position and set up

- If applicable, tourniquet use (location and time), antibiotics given, catheterisation, skin prep used and draping method
- Operative information:
 - incision and approach
 - findings
 - procedure (illustrate if appropriate)
 - complications or untoward events
 - implants used
 - closure and suture material used
 - dressing
- Postoperative instructions:
 - observations and frequency
 - possible complications and required action
 - specific treatment, e.g. intravenous fluids
 - time line for normal recovery (when to mobilise, when to resume oral intake, physiotherapy, dressing changes, etc.)
 - discharge and follow-up details (including instruction for sutures, casts, etc.).

Perioperative management of the high-risk surgical patient

LEARNING OBJECTIVES

To understand:

- Factors that place patients at a high risk of complications
- Importance of identifying the high-risk patient
- Role of preoptimisation in minimising risk
- Importance of critical care in management

INTRODUCTION

In modern day medicine, the majority of patients enjoy a safe and uneventful recovery following surgery. There remains, however, a subgroup at higher risk of morbidity and mortality after surgery. Operative mortality is more meaningfully expressed in terms of deaths occurring during surgery and up to 28–30 days after surgery. The overall 30-day mortality risk for operative procedures in Western Europe is 0.7–1.85 per cent, but this figure includes the high-risk patient population. Seventy per cent of all elective procedures have a mortality risk of less than 1 per cent, the high-risk group has a mortality risk in excess of 5 per cent and when the risk exceeds 20 per cent, patients are said to be at ‘extremely high risk’ (Figure 19.1). It is estimated that the high-risk group accounts for about 12.5 per cent of all surgical procedures and more than 80 per cent of deaths.

What causes these patients to be at a high risk of death and complications after surgery? After surgery tissue destruction, blood loss, fluid shifts, changes in temperature, pain and anxiety result in increased demands for oxygen delivery to the tissues. This demand increases from an average of 110 mL/m² per minute

at rest to 170 mL/m² per minute in the postoperative period. Most patients meet this increase in demand by increasing their cardiac output and tissue oxygen extraction. Failure to meet these demands as a result of a limited cardiorespiratory reserve, can lead to myocardial ischaemia and multiorgan failure. These account for the majority of predictable surgical morbidity and mortality. Cardiac and respiratory problems contribute equally to this.

CLASSIFICATION OF RISK

Risk after surgery is a complex interaction of multiple factors which can be classified into patient and surgical factors (Table 19.1). The elderly, though not independently at higher risk, not only suffer more cardiac, pulmonary and renal disease, but also require surgery four times as often as the rest of the population.

The type of surgery contributes independently, but patient factors are probably more important as shown by the mortality rates of patients in different categories of fitness (Table 19.2). This risk increases if the surgery is performed as an emergency. Often, the underlying condition necessitating surgery itself may be associated with an increased risk of complications. For example, a patient with severe peripheral vascular disease resulting from heavy smoking, may need a femoral-popliteal bypass graft and can be expected also to have significant chronic obstructive pulmonary disease (COPD) and ischaemic heart disease (IHD).

Moreover, when mortality by type of surgery is adjusted for patient risk factors, the apparent hierarchy of surgical risk may change. The average mortality risk for an individual patient undergoing thoracic surgery, for example, is likely to be higher than the average risk for that same patient undergoing vascular surgery. Complications associated with the latter are nevertheless more frequent because vascular patients have greater medical risk factors (Table 19.3).

The typical high-risk patient is the elderly patient with coexisting conditions, such as IHD and/or COPD, undergoing major surgery. The risk would increase if the surgery is performed as an emergency.

Figure 19.1 Size and mortality rates for different populations of surgical patients.

Table 19.1 Factors that predispose patients to a high risk of morbidity and mortality.

Patient factors	History of severe cardiac disease (ischaemic heart disease (IHD), myocardial infarction (MI), cardiac failure) Severe respiratory disease (chronic obstructive pulmonary disease (COPD), respiratory failure) Aged >70 years with limited physiological reserve in one or more vital organs Metabolic disease (renal failure, poorly controlled diabetes) Morbid obesity Late stage vascular disease Poor nutrition
Surgical factors	Prolonged duration of surgery (>1.5 hours) Extensive surgery (e.g. oesophagectomy, gastrectomy) Type of surgery (thoracic, abdominal, vascular) Emergency surgery (e.g. perforated viscus, gangrenous bowel, gastrointestinal bleeding) Acute massive blood loss (>2.5 litres) Septicaemia (positive blood cultures or septic focus) Severe multiple trauma e.g. >3 organs or >2 systems or ≥2 body cavities open

Adapted from criteria outlined by Shoemaker and colleagues and Mangano and colleagues.

Table 19.2 Operative mortality by ASA (American Society of Anesthesiologists) grade.

ASA grade	Description	30-day mortality (%)
I	Healthy	0.1
II	Mild systemic disease, no functional limitation	1
III	Severe systemic disease, definite functional limitation	4
IV	Severe systemic disease, constant threat to life	20
V	Moribund patient unlikely to survive 24 hours with or without operation	90
E	Emergency operation	–

Table 19.3 The effect of adjustment for patient factors on surgery-specific operative mortality (modified from Noordzij *et al.*, 2010).

Type of surgery	Unadjusted 30-day mortality (% (rank))	Adjusted 30-day mortality (% (rank))
Vascular	6.0 (1)	1.0 (5)
Thoracic	3.4 (2)	2.3 (1)
Abdominal	2.7 (3)	1.8 (2)
Cardiac	2.7 (4)	1.1 (4)
Neurosurgery	1.7 (5)	1.6 (3)
Orthopaedic	1.3 (6)	0.5 (7)
ENT	0.9 (7)	0.7 (6)
Urology	0.8 (8)	0.4 (8)
Gynaecology	0.1 (9)	0.2 (9)
Breast	0.7 (10)	0.1 (10)

GENERAL PRINCIPLES OF MANAGEMENT

The key to managing these patients is the identification of risk, the accurate estimation of that risk and the work done to minimise it.

Realistic estimates of risk are the cornerstone of informed patient consent. The patient and the surgeon may choose a less extensive or even a non-surgical option where risks of the definitive procedure are deemed to be too high or unacceptable. Senior staff, both surgical and anaesthetic, should be involved in these cases from the start and surgery should be performed during normal working hours wherever possible.

Depending on particular comorbidities, it may be possible for a patient's underlying conditions to be improved by optimising their medical therapy. Additional physiological optimisation may take the form of measures to minimise myocardial ischaemia or measures to improve oxygen delivery to the other major organs, depending on the prevailing risks. Optimisation before surgery can be more effective in a critical care environment and patients may need to be admitted to a high dependency unit (HDU) or intensive treatment unit (ITU) preoperatively. The likelihood of the high-risk patient requiring postoperative critical care should be discussed with the duty critical care physician.

Identification of patients who will benefit most from these additional considerations is important not only for the improvement of outcomes, but also the effective allocation of resources. Emergency surgery is associated with higher risks because by its very nature, there is less time and opportunity to organise these additional levels of care (Summary box 19.1).

Summary box 19.1

A practical approach to perioperative care for the high-risk patient

- Identify the high-risk patient
- Assess the level of risk
- Detailed preoperative assessment
- Optimise medical management
- Intraoperative considerations
- Consider specific strategies, e.g. β -blockade or goal-directed therapy
- Consider admission to a critical care facility postoperatively

Identification of the high-risk patient

A number of scoring systems have been developed over the years with the aim of identifying high-risk patients (Table 19.4).

The ASA (American Society of Anesthesiologists) scoring system is widely used and is simple and related to operative mortality (Table 19.2), but does not take into account age or nature of surgery and is prone to user interpretation.

More may be gleaned from a subjective estimate of the patient's overall functional physical fitness as judged by their ability to tolerate metabolic equivalent tasks (METs) (Table 19.5). Objective indices based on weighted scores pertaining to surgery and comorbidity have been created to stratify cardiac risk, such as the Goldman cardiac risk index and the revised cardiac risk index (RCRI) of Lee (Table 19.6), which although designed to predict cardiac morbidity, may also be used to stratify the risk of mortality.

Lee Goldman, born 1948, Dean of Health Sciences and Medicine, Columbia University, New York, USA, since 2006. He developed his Index in 1977.

Thomas H Lee, contemporary, Professor of Medicine, Harvard Medical School, Professor of Health Policy and Management, Harvard School of Public Health, Boston, Mass., USA.

Table 19.4 Risk scoring systems.

ASA is simple, but subject to user interpretation
MET measures exercise tolerance related to daily living
RCRI used to predict cardiac risk for non-cardiac surgery
POSSUM can only be used postoperatively and better for some types of surgery, e.g. colorectal, vascular
CPET is non-invasive, objective and becoming increasingly popular

ASA, American Society of Anesthesiologists; CPET, cardiopulmonary exercise testing; MET, metabolic equivalent of task; RCRI, revised cardiac risk index; POSSUM, Physiologic and Operative Severity Score for the enUmeration of Mortality and Morbidity.

Table 19.5 Metabolic equivalent of task (MET).

1 MET = 3.5 mL O ₂ /kg per minute (oxygen consumption by 40 year, 70 kg man at rest)
1 MET = eating and dressing
4 MET = climbing two flights of stairs
6 MET = short run
>10 MET = able to participate in strenuous sport
Patients who can exercise at 4 METS or above have lower risk of perioperative mortality

Table 19.6 The revised cardiac risk index of Lee.

Number of risk factors	Risk of major cardiac complications (%)
------------------------	---

Risk of complications according to number of risk factors

0	0.4
1	0.9
2	7.0
3+	11

Risk factors

History of ischaemic heart disease
History of compensated or prior heart failure
History of cerebrovascular disease
Diabetes mellitus
Renal insufficiency (creatinine > 177 µmol/litre)
High risk surgery

Another widely used scoring system is POSSUM (Physiologic and Operative Severity Score for the enUmeration of Mortality and Morbidity) for predicting all-cause mortality in postoperative critical care patients, as well as non-cardiac morbidity. POSSUM can, however, only be calculated after surgery and appears to be more useful for some types of surgery than others.

In recent years, cardiopulmonary exercise testing (CPET) has become a popular screening tool to identify high-risk patients. O₂ consumption and CO₂ production of the subject are measured while they undergo a 10-minute period of incrementally demanding exercise (usually on a cycle ergometer) up to their maximally tolerated level (Figure 19.2).

**Figure 19.2** Cardiopulmonary exercise testing (CPET).

CPET is based on the principle that when a subject's delivery of O₂ to active tissues becomes inadequate, anaerobic metabolism begins; lactate is buffered by bicarbonate and the resulting CO₂ increases out of proportion to the escalation in physical difficulty and O₂ consumption. The 'anaerobic threshold' (AT) is the O₂ consumption in mL/kg per minute above which this occurs. Peak oxygen consumption (VO₂) is also measured. They are the end product of a subject's combined respiratory, cardiac, vascular and musculoskeletal fitness, and subjects with either an AT below a somewhat arbitrary cut-off of 11 and a VO₂ below 15 mL/kg per minute are at higher risk of morbidity and mortality after surgery (Summary box 19.2).

Summary box 19.2

Risk scoring systems

- ASA is simple but subject to user interpretation
- RCRI used to predict cardiac risk for non-cardiac surgery
- POSSUM can only be used postoperatively and is better for some surgery e.g. colorectal, vascular
- CEPT is a non-invasive and objective method

Optimise medical management of coexisting diseases and intraoperative considerations

The medical management of all coexisting disease processes should be reviewed and optimised. The actions taken may be simple measures, such as stopping smoking, reducing alcohol intake, losing weight, improving nutrition and/or haemoglobin levels. In some cases, there will be a need for more complex investigations, review of medication or even consideration of further surgery. Patients scheduled for abdominal aortic aneurysm (AAA) repair surgery for example, frequently require carotid duplex scans. If the scans reveal a significant blockage and a high risk of perioperative stroke, a carotid endarterectomy may be indicated prior to AAA repair. All high-risk patients

benefit from multidisciplinary team care and the involvement of experienced physicians in the perioperative period. The impact and management of the comorbidities which commonly contribute to risk are outlined below.

Ischaemic heart disease

Perioperative myocardial infarction (MI) is associated with a high mortality (15–25 per cent). Ischaemia and ultimately MI occur when the supply of oxygen to the myocardium is exceeded by its demand. This situation can be precipitated by hypotension, tachycardia and procoagulant states (of which the inflammatory response to surgery is an example).

Preparation of these patients for surgery should be aimed at optimising their myocardial oxygen supply and demand ratio and so minimise the risk of myocardial ischaemia developing. This work may involve further investigations or even the decision to postpone non-cardiac surgery for three to six months after an MI.

Minimising myocardial ischaemia

Anaesthesia techniques that dampen the stress response to surgery (especially minimising pain) and provide a good degree of cardiac stability should be used. Anaesthesia should avoid tachycardia, systolic hypertension and diastolic hypotension and may be aided by use of invasive arterial blood pressure monitoring to facilitate this. Blood loss must be accurately monitored and haemoglobin maintained at a level suitable for the patient's cardiac risk factors. Perioperative use of β -blockers may be considered, but this is controversial and is discussed below under Prophylactic β -blockade.

Troponin testing allows early diagnosis of perioperative MIs, but there are limited reperfusion options due to risk of bleeding from the surgical site. Admission to a HDU should be considered for patients with IHD and supplemental oxygen therapy continued for 3 to 4 days (Summary box 19.3).

Summary box 19.3

Minimising myocardial ischaemia

- Anaesthesia should avoid tachycardia, hypertension and hypotension
- Pain control is important
- Oxygen supplementation is advisable for 3–4 days postoperatively
- Perioperative β -blockade should be considered
- Elective postoperative critical care admission should be considered

Cardiac failure

Left ventricular failure is the end result of several conditions including IHD, hypertension, cardiomyopathies and valve dysfunction. Decompensated heart failure puts patients at a risk of multiorgan failure and those with ejection fractions of less than 35 per cent and in whom the failure is undiagnosed or its severity underestimated are at the highest risk. The patient's functional capacity needs to be assessed and surgery may have to be delayed for investigations such as an echocardiogram and/or for optimisation of medical therapy. Drugs used in chronic heart failure have significant implications for perioperative care and

β -blockers and probably ACE inhibitors (unless renal perfusion is to be significantly affected) should be continued. Anaesthesia should ensure minimal myocardial depression and change in afterload during surgery. Arrhythmias must be rapidly brought under control, particularly atrial fibrillation (AF), and correcting any electrolyte imbalance is crucial in this respect. Invasive monitoring of trends in central venous and arterial pressure monitoring may help management, particularly when large fluid shifts are expected to occur.

Respiratory failure

Surgery, particularly open abdominal procedures under general anaesthesia result in changes to respiratory physiology. The functional residual capacity of the lungs is reduced. This combined with respiratory depressant effects of residual anaesthetic agents, the patient's limited mobility, and pain from surgery causes atelectasis (failure of gas exchange due to alveolar collapse) and predisposes patients to postoperative respiratory infection. Together with other complications, including bronchospasm, pneumothorax and acute respiratory distress syndrome (ARDS), these contribute as much to morbidity and length of hospital stay as cardiac complications. Respiratory failure defined as a $\text{PaO}_2 < 8 \text{ kPa}$ in air, $\text{PaO}_2/\text{FiO}_2 < 40 \text{ kPa}$ or inability to extubate a patient 48 hours after surgery, is by far the most significant of these and is associated with a mortality of 27–40 per cent.

Again, as with cardiac risk management, it may be necessary to postpone surgery to allow medical optimisation or consider a non-operative option. Preoperatively, bronchodilator therapy will be required in those with reversible obstructive airway disease and steroids may need to be started or increased. Nutritional status should be optimised and albumin levels corrected. Physiotherapy for postural drainage and deep breathing exercises or incentive spirometry should be considered for patients at increased risk of respiratory complications. General anaesthesia is associated with more respiratory complications and so regional techniques should be considered where possible in these patients. Hypoxaemia and CO_2 retention leading to the need for reintubation is better avoided in those at risk, by delaying extubation until analgesia, hydration and acid-base status have been corrected. Patients may benefit from ITU admission and this needs planning. Application of non-invasive respiratory support (Figure 19.3) may allow certain patients to be extubated earlier (Summary box 19.4).

Summary box 19.4

Optimising perioperative respiratory function

- Preoperative pulmonary function needs testing to assess functional status
- Consider bronchodilator \pm steroid therapy
- Arrange pre- and postoperative chest physiotherapy and breathing exercises
- Consider regional anaesthesia
- Give good quality pain relief
- Use non-invasive ventilation strategies

Other comorbidities

Acute renal failure, chronic kidney disease, diabetes, peripheral vascular disease and liver dysfunction are some of the medical conditions that contribute to risk and need to be optimised.

Figure 19.3 Non-invasive ventilation.

SPECIFIC STRATEGIES

Prophylactic β -blockade

A number of studies have considered the prophylactic use of nitrates, calcium channel blockers and β -blockers for patients at high risk of perioperative myocardial ischaemia. With the exception of β -blockade, none of these therapies has resulted in an improvement in outcome.

'POISE', a large randomised trial, looked at the use of β -blockers in the 'at risk' group undergoing non-cardiac surgery. They found that perioperative β -blockers lead to reduced deaths and MIs combined, but increased risk of hypotension, strokes and deaths overall. Patients already on β -blockers should continue taking them in the perioperative period. When β -blockers are added preoperatively, they must be titrated to heart rate and blood pressure over at least a week before surgery. Recent European guidelines may be used to determine which patients may benefit from preoperative β -blockade (see Further reading).

Goal-directed therapy

Persistent inadequate tissue perfusion is a major factor in the development of perioperative organ failure. High-risk patients who survive without multiorgan failure are known to have higher cardiac indices (CI) and oxygen delivery (DO_2) than those who die. This led to the concept of goal-directed therapy (GDT). The aim of GDT is to manipulate a patient's physiology to achieve targets that are associated with an improved outcome ($\text{CI} > 4.5 \text{ L/m}^2$ per minute, $\text{DO}_2 > 600 \text{ mL/m}^2$ per minute) using intravenous fluids and inotropes directed by measurements of cardiac output (CO).

For many years, the pulmonary artery catheter (PAC) was used to measure CO and facilitate GDT. However, it is an invasive technique associated with risks of arrhythmia, catheter knotting and pulmonary artery rupture. Thus, the need for critical care support was imperative while using PAC with subsequent resource implications.

Today, PAC has been replaced by less invasive devices to measure cardiac output, such as oesophageal Doppler, lithium dilution and pulse contour analysis equipment. The oesophageal Doppler device measures blood velocity in the aorta and then calculates the CO (Figure 19.4). Single values are inaccurate,

Figure 19.4 Oesophageal Doppler.

but as a device to monitor trends it is useful to rapidly detect CO changes in response to fluid administration. The administration of intravenous fluids to Doppler-guided targets compared to conventional replacement has been shown to reduce complications in cardiac, orthopaedic and abdominal surgery.

Some patients may need therapy with inotropes and/or vasopressors along with fluid administration. However, vasopressors increase myocardial oxygen demand and are not suitable in all patients. In addition to the above treatment, titrated doses of β -blockers can benefit those with a prevailing risk of ischaemia. Evidence is now emerging that GDT may have benefits if commenced intraoperatively and even postoperatively (Summary box 19.5).

Summary box 19.5

Specific strategies

- Initiation of perioperative β -blockade remains controversial
- Patients already taking β -blockers must continue their medication
- Less invasive modalities of CO measurement have largely superseded the PAC
- Fluids guided by GDT can reduce complications from surgery
- Inotropes and/or vasopressors are still required in many high-risk patients

MINIMISING THE IMPACT OF SURGICAL RISK FACTORS

There are situations where a choice of surgical techniques exists and which may be significantly influenced by patient risk factors. Some techniques are not primarily high-risk, but may become so in unsuitable patients. Laparoscopic surgery, for example, has come of age as a preferred technique for patients predisposed to postoperative respiratory complications, but its effect on cardiac

physiology means the same may not apply to patients at risk of cardiac complications. The expanding demand and indications for minimal access surgery are now pushing the boundaries of intraoperative physiological tolerance. Robotic prostatectomy and some laparoscopic colorectal procedures, require a pneumoperitoneum with steep Trendelenburg (head down) positioning for several hours (Figure 19.5). This can be associated with adverse cardiovascular and neurological complications, such as myocardial ischaemia and increased intracranial pressure in the high-risk group. This risk may be minimised by attention to patient selection.

Figure 19.5 Robotic surgery.

ROLE OF CRITICAL CARE AND OUTREACH SERVICES

Optimal care in the high-risk group should be extended to include postoperative support which for a majority of these patients means admission to a critical care bed. Reports from the National Confidential Enquiry into Patient Outcome and Death (NCEPOD) show that the majority of postoperative deaths in the UK occur more than 5 days after surgery. Admission to a critical care unit allows for early intervention and a level of care that is difficult to deliver in the ward environment during this crucial period (Figure 19.6). The high-risk surgical population accounts for 80 per cent of postoperative deaths, but only about 15–30 per cent of high-risk surgical patients are admitted to a critical care unit at any time following surgery. One study which compared surgical mortality in the UK and the United States found an observed mortality of 10 per cent in the UK as compared to 2 per cent in the United States. It is suggested that the difference may be related to the provision of critical care

Figure 19.6 A high-risk patient admitted to the intensive care unit post-operatively.

services, with 10 critical care beds per 100 000 population in the UK compared to 30 in the United States.

In the last decade, the role of critical care has been expanded to the concept of 'critical care without walls'. The intensive care outreach services (ICORS) grew from a recognition that there were many patients in the hospital who are at risk of being critically ill and early identification of these patients could allow for early intervention. The outreach team functions to bridge the gap between critical care unit and ward.

SUMMARY

The majority of postoperative complications and deaths after surgery occur in the high-risk population. In most instances, mortality results ultimately either from a cardiac event or multiorgan dysfunction secondary to a severe deficiency in tissue oxygen delivery. Increased awareness along with improved systems for the identification of the high-risk surgical patient are important, as today novel treatment strategies offer the prospect of significant improvements in outcome. A multidisciplinary team approach is crucial to successful management.

CHAPTER 20

Nutrition and fluid therapy

LEARNING OBJECTIVES

To understand:

- The causes and consequences of malnutrition in the surgical patient
- Fluid and electrolyte requirements in the pre- and postoperative patient
- The nutritional requirements of surgical patients and the nutritional consequences of intestinal resection
- The different methods of providing nutritional support and their complications

INTRODUCTION

Malnutrition is common. It occurs in about 30 per cent of surgical patients with gastrointestinal disease and in up to 60 per cent of those in whom hospital stay has been prolonged because of postoperative complications. It is frequently unrecognised and consequently patients often do not receive appropriate support. There is a substantial body of evidence to show that patients who suffer starvation or have signs of malnutrition have a higher risk of complications and an increased risk of death in comparison with patients who have adequate nutritional reserves.

Figure 20.1 Severely malnourished patient with wasting of fat and muscle.

Long-standing protein-calorie malnutrition is easy to recognise (Figure 20.1). Short-term undernutrition, although less easily recognised, frequently occurs in association with critical illness, major trauma, burns or surgery, and also impacts on patient recovery. The aim of nutritional support is to identify those patients at risk of malnutrition and to ensure that their nutritional requirements are met by the most appropriate route and in a way that minimises complications.

PHYSIOLOGY

Metabolic response to starvation

After a short fast lasting 12 hours or less, most food from the last meal will have been absorbed. Plasma insulin levels fall and glucagon levels rise, which facilitates the conversion of 200 g of liver glycogen into glucose. The liver, therefore, becomes an organ of glucose production under fasting conditions. Many organs, including brain tissue, red and white blood cells and the renal medulla, can initially utilise only glucose for their metabolic needs. Additional stores of glycogen exist in muscle (500 g), but these cannot be utilised directly. Muscle glycogen is broken down (glycogenolysis) and converted to lactate, which is then exported to the liver where it is converted to glucose (Cori cycle). With increasing duration of fasting (>24 hours), glycogen stores are depleted and *de novo* glucose production from non-carbohydrate precursors (gluconeogenesis) takes place, predominantly in the liver. Most of this glucose is derived from the breakdown of amino acids, particularly glutamine and alanine as

Carl Ferdinand Cori, 1896–1984, Professor of Pharmacology and later Biochemistry, Washington University Medical School, St Louis, MI, USA and his wife Gerty Theresa Cori, 1896–1957, also Professor of Biochemistry at the Washington University Medical School. In 1947, the Coris were awarded a share of the Nobel Prize for Physiology or Medicine for their discovery of how glycogen is catalytically converted.

a result of catabolism of skeletal muscle (up to 75 g per day). This protein catabolism in simple starvation is readily reversed with the provision of exogenous glucose.

With more prolonged fasting there is an increased reliance on fat oxidation to meet energy requirements. Increased breakdown of fat stores occurs, providing glycerol, which can be converted to glucose, and fatty acids, which can be used as a tissue fuel by almost all of the body's tissues. Hepatic production of ketones from fatty acids is facilitated by low insulin levels and, after 48–72 hours of fasting, the central nervous system may adapt to using ketone bodies as their primary fuel source. This conversion to a 'fat fuel economy' reduces the need for muscle breakdown by up to 55 g per day.

Another important adaptive response to starvation is a significant reduction in the resting energy expenditure, possibly mediated by a decline in the conversion of inactive thyroxine (T4) to active tri-iodothyronine (T3). Despite these adaptive responses, there remains an obligatory glucose requirement of about 200 g per day, even under conditions of prolonged fasting (Summary box 20.1).

Summary box 20.1

Metabolic response to starvation

- Low plasma insulin
- High plasma glucagon
- Hepatic glycogenolysis
- Protein catabolism
- Hepatic gluconeogenesis
- Lipolysis: mobilisation of fat stores (increased fat oxidation)–overall decrease in protein and carbohydrate oxidation
- Adaptive ketogenesis
- Reduction in resting energy expenditure (from approximately 25–30 kcal/kg per day to 15–20 kcal/kg per day)

Hepatic production of ketones from fatty acids is facilitated by low insulin levels and, after 48–72 hours of fasting, the central nervous system may adapt to using ketone bodies as their primary fuel source.

Metabolic response to trauma and sepsis

This is described in full in Chapter 1 and summarised in Summary box 20.2.

Summary box 20.2

Metabolic response to trauma and sepsis

- Increased counter-regulatory hormones: adrenaline, noradrenaline, cortisol, glucagon and growth hormone
- Increased energy requirements (up to 40 kcal/kg per day)
- Increased nitrogen requirements
- Insulin resistance and glucose intolerance
- Preferential oxidation of lipids
- Increased gluconeogenesis and protein catabolism
- Loss of adaptive ketogenesis
- Fluid retention with associated hypoalbuminaemia

From a nutritional point of view, two factors deserve emphasis. First, in contrast to simple starvation, patients with trauma have impaired formation of ketones and the breakdown of protein to synthesise glucose (gluconeogenesis) cannot be entirely

prevented by the administration of glucose. Second, although it is generally accepted that the metabolic response to trauma and sepsis is always associated with 'hypermetabolism' or hypercatabolism', these terms are ill defined and do not indicate the need for very high-energy intakes. There is no evidence to show that the provision of high-energy intakes is associated with an amelioration of the catabolic process and it may indeed be harmful.

NUTRITIONAL ASSESSMENT

Laboratory techniques

There is no single biochemical measurement that reliably identifies malnutrition. Albumin is not a measure of nutritional status. Although a low serum albumin level (<30 g/L) is an indicator of poor prognosis, hypoalbuminaemia invariably occurs because of alterations in body fluid composition and because of increased capillary permeability related to ongoing sepsis. Malnutrition is associated with defective immune function, and measurement of lymphocyte count and skin testing for delayed hypersensitivity frequently reveal abnormalities in malnourished patients. Immunity is not, however, a precise or reliable indicator of nutritional status, nor is it a practical method in routine clinical practice.

Body weight and anthropometry

A simple method of assessing nutritional status is to estimate weight loss. Measured body weight is compared with ideal body weight obtained from tables or from the patient's usual or pre-morbid weight. Unintentional weight loss of more than 10 per cent of a patient's weight in the preceding six months is a good prognostic indicator of poor outcome. Body weight is frequently corrected for height, allowing calculation of the body mass index (BMI, defined as body weight in kilograms divided by height in metres squared). A BMI of less than 18.5 indicates nutritional impairment and a BMI below 15 is associated with significant hospital mortality. Major changes in fluid balance, which are common in critically ill patients, may make body weight and BMI unreliable indicators of nutritional status.

Anthropometric techniques incorporating measurements of skinfold thicknesses and mid-arm circumference permit estimations of body fat and muscle mass, and these are indirect measures of energy and protein stores. These measurements are, however, insufficiently accurate in individual patients to permit planning of nutritional support regimens. Similarly, use of bioelectrical impedance analysis (BIA) permits estimation of intra- and extracellular fluid volumes. These techniques are only useful if performed frequently on a sequential basis in individual patients. All of these techniques are significantly impaired by the presence of oedema.

Clinical

The possibility of malnutrition should form part of the work up of all patients. A clinical assessment of nutritional status involves a focused history and physical examination, an assessment of risk of malabsorption or inadequate dietary intake and selected laboratory tests aimed at detecting specific nutrient deficiencies. This is termed 'subjective global assessment' and encompasses historical, symptomatic and physical parameters. Recently, the British Association of Parenteral and Enteral Nutrition introduced a malnutrition universal screening tool

(MUST), which is a five-step screening tool to identify adults who are malnourished or at risk of undernutrition (Figure 20.2).

FLUID AND ELECTROLYTES

Fluid intake is derived from both exogenous (consumed liquids) and endogenous (released during oxidation of solid foodstuffs) fluids. The average daily water balance of a healthy adult is shown in Table 20.1.

Fluid losses occur by four routes:

- 1 **Lungs.** About 400 mL of water is lost in expired air each 24 hours. This is increased in dry atmospheres or in patients with

a tracheostomy, emphasising the importance of humidification of inspired air.

- 2 **Skin.** In a temperate climate, skin (i.e. sweat) losses are between 600 and 1000 mL/day.
- 3 **Faeces.** Between 60 and 150 mL of water are lost daily in patients with normal bowel function.
- 4 **Urine.** The normal urine output is approximately 1500 mL/day and, provided that the kidneys are healthy, the specific gravity of urine bears a direct relationship to volume. A minimum urine output of 400 mL/day is required to excrete the end products of protein metabolism.

Maintenance fluid requirements are calculated approximately from an estimation of insensible and obligatory losses. Various formulae are available for calculating fluid replacement based on a patient's weight or surface area. For example, 30–40 mL/kg gives an estimate of daily requirements.

The following are the approximate daily requirements of some electrolytes in adults:

- sodium: 50–90 mM/day;
- potassium: 50 mM/day;
- calcium: 5 mM/day;
- magnesium: 1 mM/day.

The nature and type of fluid replacement therapy will be determined by individual patient needs. The composition of some commonly used solutions is shown in Table 20.2.

Table 20.1 Average daily water balance of a healthy adult in a temperate climate (70 kg).

Output	Volume (mL)	Intake	Volume (mL)
Urine	1500	Water from beverage	200
Insensible losses	900	Water from food	1000
Faeces	100	Water from oxidation	300

The MUST Tool

*If height, weight or weight loss cannot be established, use documented or recalled values (if considered reliable). When measured or recalled height cannot be obtained, use knee height as surrogate measure.

If neither can be calculated, obtain an overall impression of malnutrition risk (low, medium, high) using the following:

- (i) Clinical impression (very thin, thin, average, overweight);
- (iia) Clothes and/or jewellery have become loose fitting;
- (iib) History of decreased food intake, loss of appetite or dysphagia up to 3–6 months;
- (iic) Disease (underlying cause) and psychosocial/physical disabilities likely to cause weight loss.

† Involves treatment of underlying condition, and help with food choice and eating when necessary (also applies to other categories).

Figure 20.2 The malnutrition universal screening tool (MUST) for adults (adapted from Elia M (ed.). *The MUST Report. Development and use of the 'malnutrition universal screening tool' (MUST) for adults*. A report by the Malnutrition Advisory Group of the British Association for Parenteral and Enteral Nutrition. Report No. 152, 2003, ISBN 1 899467 70X).

Table 20.2 Composition of crystalloid and colloid solutions (mmol/L).

Solution	Na	K	Ca	Cl	Lactate	Colloid
Hartmann's	131	5	2	111	29	
Normal saline (0.9% NaCl)	154	154				
Dextrose saline (4% dextrose in 0.18% saline)	30	30				
Gelofusine	150	150				Gelatin 4%
Haemacel	145	5.1	<1	145		Polygelin 75g/L
Hetastarch						Hydroxyethyl starch 6%

Note that Hartmann's solution also contains lactate 29 mmol/L. Dextrose solutions are also commonly employed. These provide water replacement without any electrolytes and with modest calorie supplements (1 litre of 5 per cent dextrose contains 400 kcal). A typical daily maintenance fluid regimen would consist of a combination of 5 per cent dextrose with either Hartmann's or normal saline to a volume of 2 litres.

There has been much controversy in the literature regarding the respective merits of crystalloid versus colloid replacement. There is no consensus on this topic and the usual advice is to replace like with like. If the haematocrit is below 21 per cent, blood transfusion may be required. There is increasing recognition, however, that albumin infusions are of little value.

In addition to maintenance requirements, 'replacement' fluids are required to correct pre-existing deficiencies and 'supplemental' fluids are required to compensate for anticipated additional intestinal or other losses. The nature and volumes of these fluids are determined by:

- A careful assessment of the patient including pulse, blood pressure and central venous pressure, if available. Clinical examination to assess hydration status (peripheries, skin turgor, urine output and specific gravity of urine), urine and serum electrolytes and haematocrit.
- Estimation of losses already incurred and their nature: for example, vomiting, ileus, diarrhoea, excessive sweating or fluid losses from burns or other serious inflammatory conditions.
- Estimation of supplemental fluids likely to be required in view of anticipated future losses from drains, fistulae, nasogastric tubes or abnormal urine or faecal losses.
- When an estimate of the volumes required has been made, the appropriate replacement fluid can be determined from a consideration of the electrolyte composition of gastrointestinal secretions. Most intestinal losses are adequately replaced with normal saline containing supplemental potassium (Table 20.3).

NUTRITIONAL REQUIREMENTS

Total enteral or parenteral nutrition necessitates the provision of the macronutrients, carbohydrate, fat and protein, together with vitamins, trace elements, electrolytes and water. When planning a feeding regimen, the patient should be weighed and an assessment made of daily energy and protein requirements. Standard tables are available to permit these calculations.

Daily needs may change depending on the patient's condition. Overfeeding is the most common cause of complications, regardless of whether nutrition is provided enterally or parenterally. It is essential to monitor daily intake to provide an assess-

Table 20.3 Composition of gastrointestinal secretions (mmol/L).

	Na	K	Cl	HCO ₃
Saliva	10	25	10	30
Stomach	50	15	110	–
Duodenum	140	5	100	–
Ileum	140	5	100	30
Pancreas	140	5	75	115
Bile	140	5	100	35

ment of tolerance. Failure to do so is the most common reason for inadequate nutrition. In addition, regular biochemical monitoring is mandatory (Table 20.4).

Macronutrient requirements

Energy

The total energy requirement of a stable patient with a normal or moderately increased need is approximately 20–30 kcal/kg per day. Very few patients require energy intakes in excess of 2000 kcal/day. Thus, in the majority of hospitalised patients in whom energy demands from activity are minimal, total energy requirements are approximately 1300–1800 kcal/day.

Table 20.4 Monitoring feeding regimens.

Daily	Body weight Fluid balance Full blood count, urea and electrolytes Blood glucose Electrolyte content and volume of urine and/or urine and intestinal losses Temperature
Weekly (or more frequently if clinically indicated)	Urine and plasma osmolality Calcium, magnesium, zinc and phosphate Plasma proteins including albumin Liver function tests including clotting factors Thiamine Acid-base status Triglycerides
Fortnightly	Serum vitamin B12 Folate Iron Lactate Trace elements (zinc, copper, manganese)

Carbohydrate

There is an obligatory glucose requirement to meet the needs of the central nervous system and certain haematopoietic cells, which is equivalent to about 2 g/kg per day. In addition, there is a physiological maximum to the amount of glucose that can be oxidised, which is approximately 4 mg/kg per minute (equivalent to about 1500 kcal/day in a 70-kg person), with the non-oxidised glucose being primarily converted to fat. However, optimal utilisation of energy during nutritional support is ensured by avoiding the infusion of glucose at rates approximating physiological maximums. Plasma glucose levels provide an indication of tolerance. Avoid hyperglycaemia. Provide energy as mixtures of glucose and fat. Glucose is the preferred carbohydrate source.

Fat

Dietary fat is composed of triglycerides of predominantly four long-chain fatty acids. There are two saturated fatty acids (palmitic (C16) and stearic (C18)) and two unsaturated fatty acids (oleic (C18 with one double bond) and linoleic (C18 with two double bonds)). In addition, smaller amounts of linolenic acid (C18 with three double bonds) and medium-chain fatty acids (C6–C10) are contained in the diet.

The unsaturated fatty acids, linoleic and linolenic acid, are considered essential because they cannot be synthesised *in vivo* from non-dietary sources. Both soybean and sunflower oil emulsions are rich sources of linoleic acid and provision of only 1 litre of emulsion per week avoids deficiency. Soybean emulsions contain approximately 7 per cent alpha-linolenic acid (an omega-3 fatty acid). The provision of fat as a soybean oil-based emulsion on a regular basis will obviate the risk of essential fatty acid deficiency.

Safe and non-toxic fat emulsions based upon long-chain triglycerides (LCTs) have been commercially available for over 30 years. These emulsions provide a calorically dense product (9 kcal/g) and are now routinely used to supplement the provision of non-protein calories during parenteral nutrition. Energy during parenteral nutrition should be given as a mixture of fat together with glucose. There is no evidence to suggest that any particular ratio of glucose to fat is optimal as long as under all conditions the basal requirements for glucose (100–200 g/day) and essential fatty acids (100–200 g/week) are met. This 'dual energy' supply minimises metabolic complications during parenteral nutrition, reduces fluid retention, enhances substrate utilisation (particularly in the septic patient) and is associated with reduced carbon dioxide production.

Concerns have been expressed about the possible immunosuppressive effects of LCT emulsions. These are more likely to occur if the recommended infusion rates (0.15 g/kg per hour) are exceeded. Nonetheless, these concerns have prompted the development of newer emulsions based upon medium-chain triglycerides, omega-3 fatty acids and, most recently, structured triglycerides, which combine long- and medium-chain triglycerides in the same emulsion. The evidence of clinical benefit for these emulsions compared with conventional LCTs is tenuous, particularly if infusion rates are appropriate and hypertriglyceridaemia is avoided.

Protein

The basic requirement for nitrogen in patients without pre-existing malnutrition and without metabolic stress is 0.10–0.15 g/kg

per day. In hypermetabolic patients, the nitrogen requirements increase to 0.20–0.25 g/kg per day. Although there may be a minority of patients in whom the requirements are higher, such as after acute weight loss when the objective of therapy is long-term repletion of lean body mass, there is little evidence that the provision of nitrogen in excess of 14 g/day is beneficial.

Vitamins, minerals and trace elements

Whatever the method of feeding, these are all essential components of nutritional regimens. The water-soluble vitamins B and C act as coenzymes in collagen formation and wound healing. Postoperatively, the vitamin C requirement increases to 60–80 mg/day. Supplemental vitamin B12 is often indicated in patients who have undergone intestinal resection or gastric surgery and in those with a history of alcohol dependence. Absorption of the fat-soluble vitamins A, D, E and K is reduced in steatorrhea and the absence of bile.

Sodium, potassium and phosphate are all subject to significant losses, particularly in patients with diarrhoeal illness. Their levels need daily monitoring and appropriate replacement.

Trace elements may also act as cofactors for metabolic processes. Normally, trace element requirements are met by the delivery of food to the gut and so patients on long-term parenteral nutrition are at particular risk of depletion. Magnesium, zinc and iron levels may all be decreased as part of the inflammatory response. Supplementation is necessary to optimise utilisation of amino acids and to avoid refeeding syndrome.

FLUID AND NUTRITIONAL CONSEQUENCES OF INTESTINAL RESECTION

Up to 50 per cent of the small intestine can be surgically removed or bypassed without permanent deleterious effects. With extensive resection (<150 cm of remaining small intestine), metabolic and nutritional consequences arise, resulting in the disease entity known as short bowel syndrome. The clinical presentation of patients with short bowel syndrome is dependent upon the nature and extent of intestinal resection.

Small bowel motility

Small bowel motility is three times slower in the ileum than in the jejunum. In addition, the ileocaecal valve may slow transit. The adult small bowel receives 5–6 litres of endogenous secretions and 2–3 litres of exogenous fluids per day. Most of this is reabsorbed in the small bowel. In the jejunum, the cellular junctions are leaky and jejunal contents are always isotonic. Fluid absorption in this region of bowel is inefficient compared with the ileum. It has been estimated that the efficiency of water absorption is 44 and 70 per cent of the ingested load in the jejunum and ileum, respectively. The corresponding figures for sodium are 13 and 72 per cent, respectively. It can be seen, therefore, that the ileum is critical in the conservation of fluid and electrolytes (Table 20.5).

Ileum

The ileum is the only site of absorption of vitamin B12 and bile salts. Bile salts are essential for the absorption of fats and fat-soluble vitamins. The enterohepatic circulation of bile salts is critical to maintain the bile salt pool. Following resection of

the ileum, the loss of bile salts increases and is not met by an increase in synthesis. Depletion of the bile salt pool results in fat malabsorption. In addition, loss of bile salts into the colon affects colonic mucosa, causing a reduction in salt and water absorption, which increases stool losses.

Colon

Transit times in the colon vary between 24 and 150 hours. The efficiency of water and salt absorption in the colon exceeds 90 per cent. Another important colonic function is the fermentation of carbohydrates to produce short-chain fatty acids. These have two important functions: first, they enhance water and salt absorption from the colon and, second, they are trophic to the colonocyte.

Effects of resection

Resection of proximal jejunum results in no significant alterations in fluid and electrolyte levels as the ileum and colon can adapt to absorb the increased fluid and electrolyte load. Absorption of nutrients occurs throughout the small bowel and resection of jejunum alone results in the ileum taking over this lost function. In this situation, there is no malabsorption.

Resection of ileum results in a significant enhancement of gastric motility and acceleration of intestinal transit. Following ileal resection, the colon receives a much larger volume of fluid and electrolytes and it also receives bile salts, which reduce its ability to absorb salt and water, resulting in diarrhoea. Even the loss of 100 cm of ileum causes steatorrhoea, which may necessitate the administration of oral cholestyramine to bind bile salts. With larger resections (>100 cm) dietary fat restriction may be necessary. Regular parenteral vitamin B12 is required.

The most challenging patients are those with short bowel syndrome who have had in excess of 200 cm of small bowel resected together with colectomy. These patients will usually have a jejunostomy. They are conveniently divided into two groups termed 'net absorbers' and 'net secretors'. Absorbers characteristically have more than 100 cm of residual jejunum and they absorb more water and sodium from the diet than passes through the stoma. These patients can be managed without supplementary parenteral fluids.

Secretors usually have less than 100 cm of residual jejunum and lose more water and sodium from their stoma than they take by mouth. These patients require supplements. Their usual daily jejunostomy output may exceed 4 litres per 24 hours. The sodium content of jejunostomy losses or other high-output fistulae is about 90 mmol/L. Jejunal mucosa is leaky and rapid sodium fluxes occur across it. If water or any solution with a sodium concentration of less than 90 mmol/L is consumed, there is a net efflux of sodium from the plasma into the bowel lumen. It is therefore inappropriate to encourage patients with high-output jejunostomies (secretors) to drink large amounts of oral hypotonic solutions. Treatment begins with restricting the total amount of hypotonic fluids (water, tea, juices, etc.) consumed to less than a litre a day. Patients should be encouraged to take glucose and saline replacement solutions, which have a sodium concentration of at least 90 mmol/L. The World Health Organization (WHO) cholera solution has a sodium concentration of 90 mmol/L and is commonly used.

Complications of short bowel syndrome include peptic ulceration related to gastric hypersecretion, cholelithiasis because of interruption of the enterohepatic cycle of bile salts, and hyper-

oxaluria as a result of the increased absorption of oxalate in the colon predisposing to renal stones. Some patients with short bowel syndrome develop a syndrome of slurred speech, ataxia and altered affect. The cause of this syndrome is fermentation of malabsorbed carbohydrates in the colon to D-lactate and absorption of this metabolite. Treatment necessitates the use of a low carbohydrate diet.

Anti-secretory drugs reduce the amount of fluid secreted from the stomach, liver and pancreas. These include H2-receptor antagonists, proton pump inhibitors and the somatostatin analogue octreotide. Octreotide also reduces gastrointestinal motility. Anti-motility drugs include loperamide and codeinephosphate, which also decrease water and sodium output from the stoma by about 20 per cent.

ARTIFICIAL NUTRITIONAL SUPPORT

The indications for nutritional support are simple. Any patient who has sustained 5–7 days of inadequate intake or who is anticipated to have no intake for this period should be considered for nutritional support. The periods may be less in patients with pre-existing malnutrition. This concept is important because it emphasises that the provision of nutritional support is not specific to certain conditions or diseases. Although patients with Crohn's disease or pancreatitis, or those who have undergone gastrointestinal resections, may frequently require nutritional support, it is the fact that they have had inadequate intakes for defined periods that is the indication rather than the specific disease process.

Enteral nutrition

The term 'enteral feeding' means delivery of nutrients into the gastrointestinal tract. The alimentary tract should be used whenever possible. This can be achieved with oral supplements (sip

Figure 20.3 Techniques used for adjuvant nutritional support. PPN, partial parenteral nutrition; TPN, total parenteral nutrition. Redrawn with permission from Rick Tharp, rxkinetics.com.

feeding) or with a variety of tube-feeding techniques delivering food into the stomach, duodenum or jejunum.

A variety of nutrient formulations is available for enteral feeding. These vary with respect to energy content, osmolarity, fat and nitrogen content and nutrient complexity; most contain up to 1–2 kcal/mL and up to 0.6 g/mL of protein. Polymeric feeds contain intact protein and hence require digestion, whereas monomeric/elemental feeds contain nitrogen in the form of either free amino acids or, in some cases, peptides. These are less palatable and are used much less frequently than in previous years. Newer feeding formulations are available that include glutamine and fibre to optimise intestinal nutrition or immunonutrients such as arginine and fish oils, but these are expensive and their use is controversial.

Sip feeding

Commercially available supplementary sip feeds are used in patients who can drink but whose appetites are impaired or in whom adequate intakes cannot be maintained with *ad libitum* intakes. These feeds typically provide 200 kcal and 2 g of nitrogen per 200 mL carton. There is good evidence to demonstrate that these sip-feeding techniques are associated with a significant overall increase in calorie and nitrogen intakes without detriment to spontaneous nutrition. The evidence that these techniques improve patient outcomes is less convincing.

Tube-feeding techniques

Enteral nutrition can be achieved using conventional nasogastric tubes (Ryle's), fine-bore feeding tubes inserted into the stomach, surgical or percutaneous endoscopic gastrostomy (PEG) or, finally, post-pyloric feeding utilising nasojejunal tubes or various types of jejunostomy. The choice of method will be determined by local circumstances and preference in many patients. Whichever method is adopted, it is important that tube feeding is supervised by an experienced dietician who will calculate the patient's requirements and aim to achieve these within 2–3 days of the instigation of feeds. Conventionally, 20–30 mL are administered per hour initially, gradually increasing to goal rates within 48–72 hours. In most units, feeding is discontinued for 4–5 hours overnight to allow gastric pH to return to normal. There is some evidence that this might reduce the incidence of nosocomial pneumonia and aspiration. There is good evidence to confirm that feeding protocols optimise the tolerance of enteral nutrition. In these, aspirates are performed on a regular basis and if they exceed 200 mL in any 2-hour period, then feeding is temporarily discontinued.

Tube blockage is common. All tubes should be flushed with water at least twice daily. If a build up of solidified diet occurs, instillation into the tube of agents such as chymotrypsin or papain may salvage a partially obstructed tube. Guidewires should not be used to clear blockages as these may perforate the tube and cause contiguous damage.

Nasogastric tubes are appropriate in a majority of patients. If feeding is maintained for more than a week or so, a fine-bore feeding tube is preferable and is likely to cause fewer gastric and oesophageal erosions. These are usually made from soft polyu-

rethane or silicone elastomer and have an internal diameter of <3 mm.

Fine-bore tube insertion

The patient should be semi-recumbent. The introducer wire is lubricated and inserted into the fine-bore tube (Figure 20.4). The tube is passed through the nose and into the stomach via the nasopharynx and oesophagus. The wire is withdrawn and the tube is taped to the patient. There is a small risk of malposition into a bronchus or of causing pneumothorax. The position of the tube should be checked using plain abdominal radiography (Figure 20.5). Alternatively, 5 mL of air can be injected and a stethoscope used to confirm bubbling from the stomach. Confirmation of position by pH testing is possible but limited by the difficulty of obtaining a fluid aspirate with narrow lumen tubes.

Gastrostomy

The placement of a tube through the abdominal wall directly into the stomach is termed 'gastrostomy'. Historically, these were created surgically at the time of laparotomy. Today, the majority are performed by percutaneous insertion under endoscopic control using local anaesthesia, known as PEG (percutaneous endoscopic gastrostomy) tubes (Figure 20.6).

Two methods of PEG are commonly used. The first is called the 'direct-stab' technique in which the endoscope is passed and the stomach filled with air. The endoscopist then watches a cannula entering the stomach having been inserted directly through the anterior abdominal wall. A guidewire is then passed through the cannula into the stomach. A gastrostomy tube (commercially available) may then be introduced into the stomach through a 'peel away' sheath. The alternative technique is the transoral or push-through technique, whereby a guidewire or suture is brought out of the stomach by the endoscope after

Figure 20.4 A fine-bore feeding tube with its guidewire.

John Alfred Ryle, 1889–1950, Regius Professor of Medicine, Cambridge University and later Professor of Social Medicine, Oxford University, Oxford, UK, introduced the Ryle's tube in 1921.

Figure 20.5 Radiograph of a tube similar to that in Figure 20.4 inserted beyond the duodenojejunal flexure.

transabdominal percutaneous insertion and is either attached to a gastrostomy tube or the tube is pushed over a guidewire. The abdominal end of the wire is then pulled, advancing the gastrostomy tube through the oesophagus and into the stomach. Continued pulling abuts it up against the abdominal wall.

If patients require enteral nutrition for prolonged periods (4–6 weeks), then PEG is preferable to an indwelling nasogastric tube; this minimises the traumatic complications related to indwelling tubes. PEG does have procedure-specific complications, although these are uncommon. Necrotising fasciitis and intra-abdominal wall abscesses have been recorded. Sepsis around the PEG site is more common and may necessitate systemic antibiotics or repositioning. A persistent gastric fistula can

Figure 20.6 Percutaneous endoscopic gastrostomy tube.

occur on removal of a PEG if it has been in place for prolonged periods and epithelialisation of the tract has occurred. This necessitates surgical closure.

Jejunostomy

In recent years, the use of jejunal feeding has become increasingly popular. This can be achieved using nasojejunal tubes or by placement of needle jejunostomy at the time of laparotomy. Some authorities advocate the use of jejunostomies on the basis that post-pyloric feeding may be associated with a reduction in aspiration or enhanced tolerance of enteral nutrition. In particular, there are many advocates of jejunostomies in patients with severe pancreatitis, in whom a degree of gastric outlet obstruction may be present, related to the oedematous head of pancreas. In most patients it is appropriate to commence with conventional nasogastric feeding and progress to post-pyloric feeding if the former is unsuccessful.

Nasojejunal tubes often necessitate the use of fluoroscopy or endoscopy to achieve placement, which may delay commencement of feeding. Surgical jejunostomies, even using commercially available needle-insertion techniques, do involve creating a defect in the jejunum, which can leak or be associated with tube displacement; both of these complications result in peritonitis.

Complications

Most complications of enteral nutrition can be avoided with careful attention to detail and appropriate infusion rates. Patients should be nursed semi-recumbent to reduce the possibility of aspiration. Complications can be divided into those resulting from intubation of the gastrointestinal tract and those related to nutrient delivery. The former are more frequent with more invasive means of gaining access to the intestinal tract (see above under Enteral nutrition). The latter include diarrhoea, bloating and vomiting. Diarrhoea occurs in more than 30 per cent of patients receiving enteral nutrition and is particularly common in the critically ill. Up to 60 per cent of patients in intensive care units may fail to receive their targeted intakes. There is no evidence that the incidence of diarrhoea and bloating is reduced by the use of half-strength feeds. It is important to introduce normal feeds at a reduced rate according to patient tolerance. Metabolic complications associated with excessive feeding are uncommon in enterally fed patients. There have been reports of nosocomial enteric infections associated with contamination of feeds, which should be kept in sealed containers at 4°C and discarded once opened. In all patients, it is essential to monitor intakes accurately as target intakes are often not achieved with enteral nutrition.

The complications of enteral nutrition are summarised in Summary box 20.3.

Parenteral nutrition

Total parenteral nutrition (TPN) is defined as the provision of all nutritional requirements by means of the intravenous route and without the use of the gastrointestinal tract.

Parenteral nutrition is indicated when energy and protein needs cannot be met by the enteral administration of these substrates. The most frequent clinical indications relate to those patients who have undergone massive resection of the small intestine, who have intestinal fistula or who have prolonged intestinal failure for other reasons.

Summary box 20.3**Complications of enteral nutrition**

- Tube-related
 - Malposition
 - Displacement
 - Blockage
 - Breakage/leakage
 - Local complications (e.g. erosion of skin/mucosa)
- Gastrointestinal
 - Diarrhoea
 - Bloating, nausea, vomiting
 - Abdominal cramps
 - Aspiration
 - Constipation
- Metabolic/biochemical
 - Electrolyte disorders
 - Vitamin, mineral, trace element deficiencies
 - Drug interactions
- Infective
 - Exogenous (handling contamination)
 - Endogenous (patient)

Route of delivery: peripheral or central venous access

TPN can be administered either by a catheter inserted in the central vein or via a peripheral line. In the early days of parenteral nutrition, the only energy source available was hypertonic glucose, which, being hypertonic, had to be given into a central vein to avoid thrombophlebitis. In the second half of the last century, there were a number of important developments that have influenced the administration of parenteral nutrition. These include the identification of safe and non-toxic fat emulsions that are isotonic; pharmaceutical developments that permit carbohydrates, fats and amino acids to be mixed in single containers; and a recognition that the provision of energy during parenteral nutrition should be a mixture of glucose and fat and that energy requirements are rarely in excess of 2000 kcal/day (25–30 kcal/kg per day). These changes enabled the development of peripheral parenteral nutrition.

Peripheral

Peripheral feeding is appropriate for short-term feeding of up to 2 weeks. Access can be achieved either by means of a dedicated catheter inserted into a peripheral vein and manoeuvred into the central venous system (peripherally inserted central venous catheter (PICC) line) or by using a conventional short cannula in the wrist veins. The former method has the advantage of minimising inconvenience to the patient and clinician. PICC lines have a mean duration of survival of 7 days. The disadvantage is that when thrombophlebitis occurs, the vein is irrevocably destroyed. In the alternative approach, intravenous nutrients are administered through a short cannula in wrist veins, infusing the patient's nutritional requirements on a cyclical basis over 12 hours. The cannula is then removed and resited in the contralateral arm. Peripheral parenteral nutrition has the advantage that it avoids the complications associated with central venous administration, but suffers the disadvantage that it is limited by the development of thrombophlebitis (Figure 20.7). Peripheral

Figure 20.7 Cycle of causes of peripheral vein thrombophlebitis (PVT) (after Payne-James J, Grimble G, Silk D (eds). *Artificial nutrition support in clinical practice*, 2nd edn. London, Greenwich Medical Media, 2001).

feeding is not indicated if patients already have an indwelling central venous line or in those in whom long-term feeding is anticipated.

Central

When the central venous route is chosen, the catheter can be inserted via the subclavian or internal or external jugular vein. There is good evidence to show that the safest means of establishing central venous access is by insertion of lines under ultrasound guidance; however, this will not be practicable for all cases. Most intensive care physicians and anaesthetists favour cannulation of internal or external jugular veins as these vessels are easily accessible. They suffer the disadvantage that the exit site is situated inconveniently on the side of the neck, where repeated movements result in disruption of the dressing with the attendant risk of sepsis. The infraclavicular subclavian approach is more suitable for feeding as the catheter then lies flat on the chest wall, which optimises nursing care (Figure 20.8).

Figure 20.8 Infraclavicular subclavian line.

For longer-term parenteral nutrition, Hickman lines are preferable. These are often inserted by a radiologist with fluoroscopic guidance or ultrasound. They incorporate a small cuff, which sits at the exit site of a subcutaneous tunnel. This is thought to minimise the possibility of line dislodgement and reduce the possibility of line sepsis. Whichever technique is employed, a post-insertion chest x-ray is essential before feeding is commenced to confirm the absence of pneumothorax and that the catheter tip lies in the distal superior vena cava to minimise the risk of central venous or cardiac thrombosis. Multi-lumen catheters can be used for the administration of TPN; one port should be employed for that sole purpose and strict protocols of care employed.

An alternative technique for central intravenous access allows the PICC technique under ultrasound guidance to cannulate the cephalic vein in the arm which facilitates passage of a catheter into the brachiocephalic vein or superior vena cava. This has many advantages as it minimises the risks of insertion and ensures distance between the site of skin entry and the tip of the catheter. Thrombophlebitis, however, can occur.

Complications of parenteral nutrition

The commencement of TPN may precipitate or accentuate underlying nutrient deficiency by encouraging anabolism. Common metabolic complications include fluid overload, hyperglycaemia, abnormalities of liver function and vitamin deficiencies. Fluid overload can be avoided by daily weighing of the patient. A weight change of >1 kg/day normally indicates fluid retention. Hyperglycaemia is common because of insulin resistance in critically ill patients. Even modest rates of glucose administration may be associated with hyperglycaemia. Hyperglycaemic patients undergoing surgery are known to run a substantially higher risk of infectious complications.

Abnormalities of liver enzymes are common in patients who are receiving TPN. Although the precise mechanisms are unclear, intrahepatic cholestasis may occur and hepatic steatosis and hepatomegaly have been reported. Reducing the fat content or infusion of fat-free TPN may be required. If liver enzymes continue to deteriorate, TPN should be temporarily discontinued. In addition, overfeeding is a major factor in hepatic and other metabolic complications associated with TPN. Supplemental parenteral glutamine during parental nutrition should be considered, particularly in the critically ill patient.

Catheter-related sepsis occurs in 3–14 per cent of patients. It may occur at the time of line insertion or afterwards by migration of skin bacteria along the external catheter surface. Some studies suggest that manoeuvring of the catheter hub due to frequent manipulation is a common cause. Contamination of the infusate is rare. Seeding on the catheter at the time of bacteraemia from a remote source may also cause catheter infection.

Diagnosis of catheter-related sepsis requires that the same organism is grown from the catheter tip as is recovered from blood and that the clinical features of infection resolve on removal of the catheter. Traditional methods of confirming line sepsis have necessitated removal of the line with subsequent bacteriological assessment. An alternative approach is to use an endoluminal brush passed down the catheter and withdrawn into a polythene sheath. The brush tip is cultured at the same time as performing blood cultures. Catheter sepsis is confirmed if identical organisms are cultured from brush and blood. A second alternative is to culture blood withdrawn through the catheter

and compare this with peripheral blood cultures. If the colony count from the catheter sample is five or more times higher than that from peripheral blood then line sepsis is probable.

The complications of parenteral nutrition are summarised in Summary box 20.4.

Summary box 20.4

Complications of parenteral nutrition

- Related to nutrient deficiency
 - Hypoglycaemia/hypocalcaemia/hypophosphataemia/hypomagnesaemia (refeeding syndrome)
 - Chronic deficiency syndromes (essential fatty acids, zinc, mineral and trace elements)
- Related to overfeeding
 - Excess glucose: hyperglycaemia, hyperosmolar dehydration, hepatic steatosis, hypercapnia, increased sympathetic activity, fluid retention, electrolyte abnormalities
 - Excess fat: hypercholesterolaemia and formation of lipoprotein X, hypertriglyceridaemia, hypersensitivity reactions
 - Excess amino acids: hyperchloraemic metabolic acidosis, hypercalcaemia, aminoacidaemia, uraemia
- Related to sepsis
 - Catheter-related sepsis
 - Possible increased predisposition to systemic sepsis
- Related to line
 - On insertion: pneumothorax, damage to adjacent artery, air embolism, thoracic duct damage, cardiac perforation or tamponade, pleural effusion, hydromediastinum
 - Long-term use: occlusion, venous thrombosis

Refeeding syndrome

This syndrome is characterised by severe fluid and electrolyte shifts in malnourished patients undergoing refeeding. It can occur with either enteral or parenteral nutrition, but is more common with the latter. It results in hypophosphataemia, hypocalcaemia and hypomagnesaemia. These electrolyte disorders can result in altered myocardial function, arrhythmias, deteriorating respiratory function, liver dysfunction, seizures, confusion, coma, tetany and death. Patients at risk include those with alcohol dependency, those suffering severe malnutrition, anorexics and those who have undergone prolonged periods of fasting. Treatment involves matching intakes with requirements and assiduously avoiding overfeeding. Calorie delivery should be increased slowly and vitamins administered regularly. Hypophosphataemia and hypomagnesaemia require treatment.

Nutrition support teams

Multidisciplinary nutrition teams ensure cost-effective and safe nutritional support, irrespective of how this is administered. The incidence of catheter-related sepsis is significantly reduced.

SUMMARY

Fluid therapy and nutritional support are fundamental to good surgical practice. Accurate fluid administration demands an understanding of maintenance requirements and an appreciation of the consequences of surgical disease on fluid losses. This requires knowledge of the consequences of surgical intervention and, in particular, intestinal resection. Malnutrition is common in hospital patients. All patients who have sustained or who are likely to sustain 7 days of inadequate oral intake should be considered for nutritional support. This may be dietetic advice alone, sip feeding or enteral or parenteral nutrition. These are not mutually exclusive. The success or otherwise of nutritional support should be determined by tolerance to nutrients provided and nutritional end points, such as weight. It is unrealistic to expect nutritional support to alter the natural history of disease. It is imperative that nutrition-related morbidity is kept to a minimum. This necessitates the appropriate selection of feeding

method, careful assessment of fluid, energy and protein requirements, which are regularly monitored, and the avoidance of overfeeding.

CHAPTER

21

Postoperative care

LEARNING OBJECTIVES

To understand:

- The system of postoperative care
- How to recognise and treat postoperative complications
- The principles of enhanced recovery
- The system for discharging patients

INTRODUCTION

The aim of postoperative care is to provide the patient with as quick, painless and safe recovery from surgery as possible. Trainees should acquire knowledge and skills to manage surgical, as well as medical, postoperative problems.

GENERAL MANAGEMENT**The immediate postoperative period: recovery room**

The theatre team should formally hand over the care of the patient to the recovery staff. The information provided should include the patient's name, age, the surgical procedure, existing medical problems, allergies, the anaesthetic and analgesics given, fluid replacement, blood loss, urine output, any surgical and anaesthetic problems encountered or expected.

Patient's vital parameters, consciousness, pain and hydration status are monitored in the recovery room and supportive treatment is given (Figure 21.1). Specific monitoring, such as Doppler flow for a free flap, observations like neurological evaluation and laboratory tests such as blood gas analysis may also be requested where necessary (Summary box 21.1).

Summary box 21.1**Postoperative period**

- All anaesthetised patients should be recovered in a recovery room.
- All vital parameters should be monitored and documented.
- Treat pain and nausea/vomiting.
- Watch for complications.

The patient can be discharged from the recovery room when they fulfil the following criteria:

- Patient is fully conscious.
- Respiration and oxygenation are satisfactory.

- Patient is normothermic, not in pain nor nauseous.
- Cardiovascular parameters are stable.
- Oxygen, fluids and analgesics have been prescribed.
- There are no concerns related to the surgical procedure.

SYSTEM-SPECIFIC POSTOPERATIVE COMPLICATIONS

The presentation of complications may be similar for more than one underlying condition. Shortness of breath can be due to respiratory or cardiac problems, abdominal pain can be due to surgical causes or sepsis, while chest pain may be present in cardiac, respiratory and even in gastrointestinal problems.

Respiratory complications

The most common respiratory complications in the recovery room are hypoxaemia, hypercapnia and aspiration. Pneumonia and pulmonary embolism tend to appear later in the postoperative period.

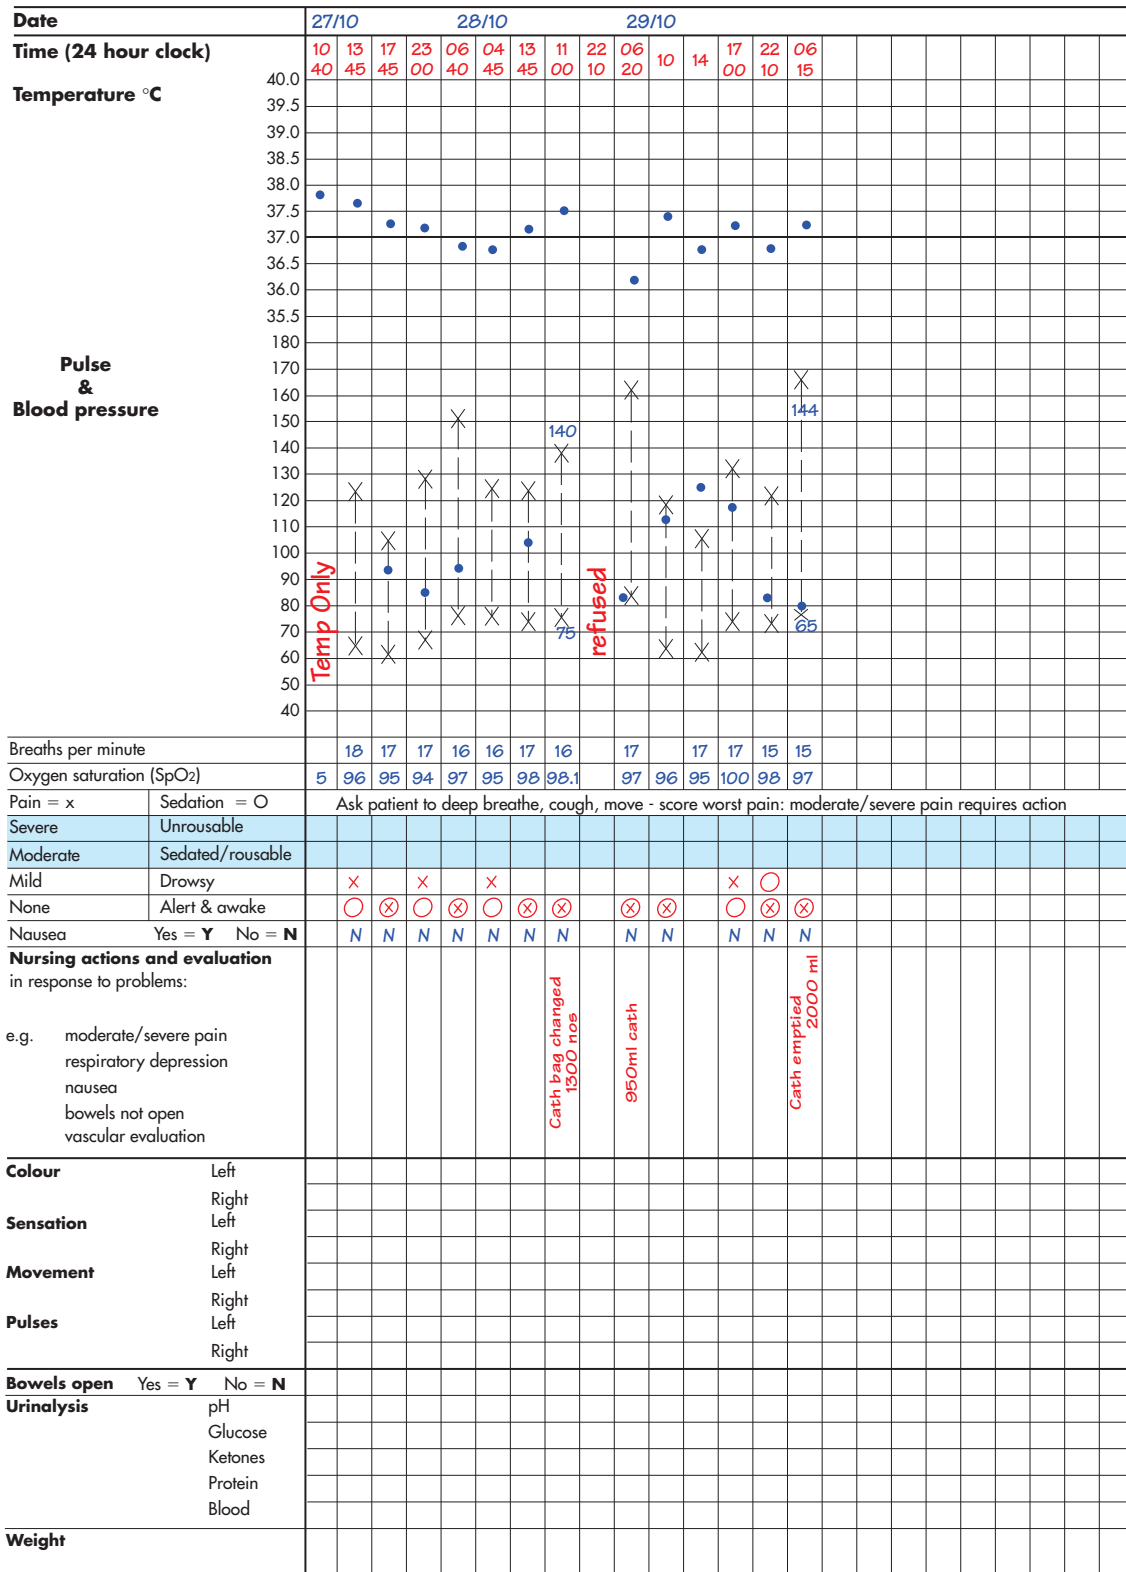

Postoperative hypoxia

Hypoxia is defined as an oxygen saturation of less than 90 per cent. Hypoxia may present as shortness of breath or agitation or as upper airway obstruction (absence of air movement, seesaw motion of chest, suprasternal recession) or cyanosis or as a combination of any of the above.

Hypoxia in the postoperative period may occur due to a variety of reasons, for example:

- Upper airway obstruction due to the residual effect of general anaesthesia, secretions or wound haematoma after neck surgery.
- Laryngeal oedema from traumatic tracheal intubation, recurrent laryngeal nerve palsy and tracheal collapse after thyroid surgery.
- Hypoventilation related to anaesthesia or surgery.
- Atelectasis and pneumonia especially after upper abdominal and thoracic surgery (Figure 21.2).
- Pulmonary oedema of cardiac origin or related to fluid overload.

OBSERVATION AND PAIN ASSESSMENT

1996/Queen's Medical Centre/Acute Pain Service

Figure 21.1 Postoperative nursing chart showing various monitoring parameters.

- Pulmonary embolism: this often presents with the sudden onset of chest pain and shortness of breath. In the presence of a large embolism, there will be systemic hypotension, pulmonary hypertension and an elevated central venous pressure (CVP) (Figure 21.3).

In obese patients or in those with acute or chronic lung disease, hypoxia develops more quickly.

Patients with hypoxia or imminent signs should be treated urgently. If the patient is breathing spontaneously administer oxygen at 15 L/min, using a non-rebreathing mask. A head tilt, chin lift or jaw thrust should relieve obstruction related to reduced muscle tone. Suctioning of any blood or secretions and insertion of an oropharyngeal airway may be needed. Call the anaesthetist as tracheal intubation and manual ventilation may also be needed.

Neck wound haematoma can become a life-threatening emergency, and must be evacuated immediately under local or general anaesthetic. Along with the immediate management of hypoxia, appropriate antibiotics, chest physiotherapy and bronchodilators will be needed to treat pneumonia. In the case of

pulmonary oedema, diuretics should be started and a cardiology opinion should be sought (Summary box 21.2).

Summary box 21.2

Respiratory complications

- Respiratory complications can occur either immediately or a few days later on the ward.
- Obese, smokers and those with chronic lung conditions are more likely to have respiratory complications.
- Early intervention and multidisciplinary involvement can prevent life threatening respiratory complications.

Cardiovascular complications

Hypotension in the immediate postoperative period may be due to inadequate fluid replacement, vasodilatation from subarachnoid and epidural anaesthesia or rewarming of the patient. However, other causes of hypotension such as surgical bleeding, sepsis, arrhythmias, myocardial infarction, cardiac failure, tension pneumothorax, pulmonary embolism, pericardial tamponade and anaphylaxis should be also sought (Figures 21.4, 21.5 and 21.6).

Patients with hypotension are likely to have cold clammy extremities, tachycardia and a low urine output ≤ 0.5 mL/kg per hour and low CVP. Hypovolaemia should be corrected with intravenous crystalloid or colloid infusions (see below under Bleeding).

Myocardial ischaemia and infarction

Patients with previous cardiac problems undergoing major surgery are at risk of developing an acute coronary syndrome. They commonly present with retrosternal pain radiating into the neck, jaw or arms and may also have nausea, dyspnoea or syncope.

Typically, there is a ST-elevation in two continuous leads on the ECG or new left bundle branch block (STEMI), though this may not always be present (non-ST-elevation

Figure 21.2 Radiograph showing right upper lobe atelectasis (courtesy of Professor Stephen Eustace, Dublin).

Figure 21.3 Computed tomography (CT) scan showing pulmonary artery blood embolism (arrow) (courtesy of Professor Stephen Eustace, Dublin).

Figure 21.4 Radiograph showing lower left lobe consolidation (courtesy of Professor Stephen Eustace, Dublin).

Figure 21.5 Radiograph showing classical *Staphylococcus aureus* pneumonia (courtesy of Professor Stephen Eustace, Dublin).

myocardial infarction (NSTEMI)). However, serum troponin levels will be high in both types of MI (myocardial ischaemia and myocardial infarction). Start treatment with oxygen, glyceryl trinitrate, morphine and aspirin and involve a cardiologist. Beta-blockers and/or calcium antagonists may be started to reduce further episodes of ischaemia. Cardiologists may start coronary reperfusion therapy for STEMI in the form of primary percutaneous coronary intervention or thrombolysis. However, these should be discussed first with a senior due to the risk of bleeding after major surgery.

Arrhythmias

Arrhythmia in the postoperative period can cause hypotension and ischaemia. Therefore, these patients will need to be continuously monitored. Treatment should be delivered according to the Resuscitation Council peri-arrest guidelines, correcting underlying causes including acid-base and electrolyte imbalance, hypoxia and hypercapnia (Summary box 21.3).

Summary box 21.3

Cardiovascular complications

- Hypotension in the postoperative period can be multifactorial
- Arrhythmias can be prevented and corrected by treating hypotension and electrolyte imbalance
- Arrhythmias and myocardial ischaemia/infarction will need management with the help of cardiologists

Tachycardia (sinus or supraventricular) may be caused by anxiety, pain, MI, hypovolaemia, sepsis or hypoxia in the postoperative period. Correct any underlying causes of the dysrhythmia and control the heart rate with beta-blockers, amiodarone or cardioversion.

Sinus bradycardia may be normal in athletes, but it may also be associated with hypoxia, preoperative beta-blockers, digoxin and increased intracranial pressure. If the heart rate is 40 bpm or less, glycopyrrolate 0.2–0.4 mg or atropine 0.6 mg should be given intravenously and the patient reviewed.

Figure 21.6 Radiograph showing a right tension pneumothorax with tracheal deviation to the left (courtesy of Professor Stephen Eustace, Dublin).

Renal and urinary complications

Acute renal failure

About a quarter of cases of hospital-acquired renal failure occur in the perioperative period and are associated with high mortality especially after cardiac and major vascular surgery (Table 21.1). Patients with known chronic renal disease, diabetes, liver failure, peripheral vascular disease and cardiac failure are at high risk. Perioperative events such as sepsis, bleeding, hypovolaemia, rhabdomyolysis or abdominal compartmental syndrome can all precipitate acute renal failure (Summary box 21.4).

Table 21.1 Common causes of acute renal failure.

Prerenal	Hypotension Hypovolaemia
Renal	Nephrotoxic drugs (gentamicin, diuretics, nonsteroidal anti-inflammatory agents) Surgery involving renal vessels Myoglobinuria Sepsis
Postrenal	Ureteric injury Blocked urethral catheter

Summary box 21.4

Renal and urinary complications

- Postoperative renal failure is associated with high mortality.
- Prophylactic measures to prevent renal failure should be taken in high risk cases.
- Urinary retention and infection are a common problem postoperatively.

If urine output is less than 0.5 mL/kg per hour for 6 hours, check that the catheter is not blocked, correct hypovolaemia, correct metabolic and electrolyte disturbances, and stop nephrotoxic drugs. Stage I of kidney failure is associated with a rise

in serum creatinine levels to more than 1.5 times baseline or a greater than 25 per cent decrease in GFR (glomerular filtration rate); aggressive treatment should be started at this early stage to avoid further damage.

Urinary retention

Inability to void after surgery is common with pelvic and perineal operations or after procedures performed under spinal anaesthesia. Pain, fluid deficiency, problems in accessing urinals and bed pans, and lack of privacy on wards may contribute to the problem of urine retention. The diagnosis of retention may be confirmed by clinical examination and by using ultrasound imaging. Catheterisation should be performed prophylactically when an operation is expected to last 3 hours or longer or when large volumes of fluid are administered.

Urinary infection

Urinary infection is one of the most commonly acquired infections in the postoperative period. Patients may present with dysuria and/or pyrexia. Immunocompromised patients, diabetics and those patients with a history of urinary retention are known to be at higher risk. Treatment involves adequate hydration, proper bladder drainage and antibiotics depending on the sensitivity of the microorganisms.

COMPLICATIONS RELATED TO SPECIFIC SURGICAL SPECIALTIES

Abdominal surgery

The abdomen should be examined daily for excessive distension, tenderness or drainage from wounds or drain sites. In certain operations, such as those for intestinal obstruction, oesophageal and gastric procedures (but not in lower intestinal operations), a nasogastric tube may be used. It is of particular value in those patients suffering from ileus or a marked level of altered consciousness who are therefore liable to aspirate.

Paralytic ileus

Paralytic ileus may present with nausea, vomiting, loss of appetite, bowel distension and absence of flatus or bowel movements. Following laparotomy, gastrointestinal motility temporarily decreases. Treatment is usually supportive with maintenance of adequate hydration and electrolyte levels. However, intestinal complications may present as prolonged ileus and so should be actively sought and treated.

Return of function of the intestine occurs in the following order: small bowel, large bowel and then stomach. This pattern allows the passage of faeces despite continuing lack of stomach emptying and, therefore, vomiting may continue even when the lower bowel has already started functioning normally.

Localised infection

An abscess may present with persistent abdominal pain, focal tenderness and a spiking fever. The patient may have a prolonged ileus. If the abscess is deep-seated, these symptoms may be absent. The patient will have a neutrophilic leukocytosis and may have positive blood cultures. An ultrasound or computed tomography (CT) scan of the abdomen should identify any suspicious collection and will identify the subphrenic abscess which can otherwise be difficult to find (Summary box 21.5).

Summary box 21.5

The main complications after abdominal surgery

- Paralytic ileus
- Bleeding or abscess
- Anastomotic leakage

Orthopaedic surgery

In patients who have undergone open reduction and internal fixation of fractures, and especially if a tourniquet has been used, the neurovascular status of the limb must be checked every half an hour first in recovery and then on the ward for at least a further 4 hours. Plasters should always be split for the first 24 hours (or until swelling starts to reduce) and the nurses given instructions to check and record distal circulation every 4 hours. If the patient has an external fixator, the pin sites should be checked daily for signs of infection.

Radiographs are taken after the operation to check that the implants are correctly positioned and that fractures remain reduced.

Patients with compartment syndrome complain of pain out of proportion to that expected. It is not relieved by simple analgesics. Passive stretching of the muscles in the affected compartment produces severe pain. The limb is usually swollen and tense and, in the later stages, there may be altered sensation distally. Distal pulses are only lost at a very late stage and so their presence does not exclude a compartment syndrome. Intracompartmental pressure studies are not reliable so should only be used in the unconscious patient. If there is any possibility that a patient might have a compartment syndrome then all circumferential dressings should be removed at once. If there is no immediate improvement in the pain, then a fasciotomy should be performed. The diagnosis is a clinical one and is made on suspicion not certainty (Summary box 21.6).

Summary box 21.6

Compartment syndrome

- Severe/greater than expected pain unresponsive to analgesia
- The earliest sign is pain on passive stretching of muscles in the affected compartment
- Paralysis, paraesthesia and pulselessness are very late signs

Neck surgery

Patients having neck surgery, e.g. thyroid surgery, must be observed for accumulation of blood in the wound, which may cause rapid asphyxia. A check also needs to be made pre- and postoperatively for damage to the recurrent laryngeal nerve. The findings must be recorded in the medical notes.

Thoracic surgery

Fluid intake should be restricted in patients undergoing a lobectomy or pneumonectomy as they are susceptible to fluid overload in the first 24–48 hours postoperatively. Chest drains require regular review. If the fluid in a chest drain swings then

the drain has been inserted correctly in the pleural cavity. If the chest drain continues to bubble, then a bronchopleural fistula probably exists. A haemothorax or pleural effusion (Figure 21.4) will reveal itself as a prolonged loss of blood or fluid, respectively, into the drain. Cardiac patients require continuous electrocardiography monitoring postoperatively (Figures 21.5, 21.6 and 21.7).

Neurosurgery

Postoperatively, the patient should be kept under close observation. A rise in intracranial pressure may be signalled by a deterioration in the state of consciousness, as well as by the appearance of new neurological signs. Some patients may have an intracranial monitoring device to allow for more sensitive monitoring.

Vascular surgery

The patency of grafts and anastomoses in patients with femoropopliteal bypasses and abdominal aneurysmal repairs needs to be checked by regular clinical assessment of the limbs and by Doppler ultrasound in the postoperative phase.

Plastic surgery

The viability of flaps is crucial and the perfusion needs to be monitored regularly. The blood supply may be compromised by position, dressings or collection of fluids or blood beneath the flap.

Urology

Catheter patency must be checked regularly following urological surgery. In patients who have undergone transurethral resection of the prostate (TURP), continuous bladder irrigation may be used, and pulmonary oedema may develop if a large amount of irrigation fluid is absorbed into the circulation.

GENERAL POSTOPERATIVE PROBLEMS AND MANAGEMENT

Pain

This is discussed in Chapter 17.

Figure 21.7 Radiograph showing a bilateral pleural effusion (courtesy of Professor Stephen Eustace, Dublin).

Fluid and nutrition

This is covered in Chapter 19.

Nausea and vomiting

Postoperative nausea and vomiting (PONV) can precipitate bleeding and dehiscence of wounds by dislodging the clots and bursting suture lines. In neurosurgical patients, it may precipitate raised intracranial pressure with disastrous effects.

Women, non-smokers or those who have a past history of PONV, motion sickness or migraine are known to have a higher risk of developing PONV. Use of volatile anaesthetic agents, opioids and nitrous oxide add to the risk. Duration and type of surgery also affect the incidence of PONV.

Adequate treatment of pain, anxiety, hypotension and dehydration will minimise the risk of the patient developing PONV. Administer antiemetics that work at different sites, such as HT3 receptor antagonists (e.g. ondansetron), steroids (e.g. dexamethasone), phenothiazines (e.g. prochlorperazine), antihistamines (e.g. cyclizine). At least one antiemetic should be given on a regular basis in the high risk group of patients and a second one written up to be given when needed.

Bleeding

The patient's blood pressure, pulse, urine output, dressings and drains should be checked regularly in the first 24 hours after surgery. If bleeding is more than expected for a given procedure, then pressure should be applied to the site and blood samples should be sent for blood count, coagulation profile and cross-match. Fluid resuscitation should also be started. Ultrasound or CT scan may need to be arranged to determine the size and extent of the haematoma. If immediate control of bleeding is essential, the patient may be taken back to the operating theatre. If surgical haemostasis is not successful using conventional methods, haemostatic dressings or surgical glue may be tried. The radiological embolisation of bleeding vessels can also prove useful.

All hospitals should have a 'major haemorrhage protocol' in place. The consultant surgeon, anaesthetist and haematologist should all be informed early about unstable patients.

In a patient with postoperative bleeding, oxygenation and fluid resuscitation should be continued, and blood or blood products given if the haemoglobin concentration is less than 8 g/dL. Serum fibrinogen levels below 1 g/L or a prothrombin time (PT) and activated partial thromboplastin time (APTT) greater than 1.5 times normal levels indicate the need for fresh frozen plasma, cryoprecipitate and fibrinogen concentrates. The platelet count should be maintained above $75 \times 10^9/L$.

The risks versus the benefits of blood transfusion should be weighed, especially if only one or two units are to be transfused.

Incompatible transfusion causes an acute haemolytic transfusion reaction. The patient may present with fever, chills and rigors, tachycardia, urticaria, body pain, respiratory distress or sudden cardiovascular collapse. If a transfusion reaction is suspected, then the transfusion should be stopped immediately, the patient resuscitated and the blood sent back to the blood bank for retesting.

Blood transfusion can lead to acute fluid overload, hyperkalaemia, severe allergic reaction or anaphylaxis, acute lung injury and delayed haemolytic reaction caused by Kidd and Rh antibodies. Transmission of hepatitis B, C, A, human immuno-

deficiency virus, cytomegalovirus and variant Creutzfeldt–Jakob disease are also possible (Summary box 21.7).

Summary box 21.7

Postoperative bleeding

- All hospitals should have a major haemorrhage protocol in place
- Need to transfuse blood in the absence of continued bleeding in patients with Hb >8 g/dL should be weighed against the risks
- Minor bleeding in an airway can have a catastrophic effect.

Deep vein thrombosis

Patients suffering postoperative deep vein thrombosis (DVT) may present with calf pain, swelling, warmth, redness and engorged veins. However, most will show no physical signs. On palpation, the muscle may be tender and there is a positive Homans' sign (calf pain on dorsiflexion of the foot), but this test is neither sensitive nor specific.

Venography or duplex Doppler ultrasound is used to assess flow and the presence of thromboses. If a significant DVT is found (one that extends above the knee), treatment with intravenous heparin initially, followed by longer-term warfarin, should be started. In some patients with a large DVT, a caval filter may be required to decrease the possibility of pulmonary embolism.

Most hospitals have a DVT prophylaxis protocol. This may include the use of stockings, calf pumps and pharmacological agents, such as low molecular weight heparin. No method of prophylaxis is foolproof and they all have their own complications, and so an optimal strategy needs to be developed, which is individualised to the patient and the operation that they are receiving (Table 21.2).

Table 21.2 Stratification of risk of deep vein thrombosis.

Low	Medium	High
Maxillofacial surgery	Inguinal hernia repair	Pelvic elective and trauma surgery
Neurosurgery	Abdominal surgery	
Cardiothoracic surgery	Gynaecological surgery	Total knee and hip replacement
	Urological surgery	

Hypothermia and shivering

Anaesthesia induces loss of thermoregulatory control. Exposure of skin and organs to a cold operating environment, volatile skin preparation (which cool by evaporation), and the infusion of cold i.v. fluids all lead to hypothermia. This, in turn, leads to increased cardiac morbidity, a hypocoagulable state, shivering with imbalance of oxygen supply and demand, and immune function impairment with the possibility of wound infection. Active warming devices should be used to treat hypothermia as appropriate.

Fever

About 40 per cent of patients develop pyrexia after major surgery; however, in most cases no cause is found. The inflam-

matory response to surgical trauma may manifest itself as fever, and so pyrexia does not necessarily imply sepsis. However, in all patients with a pyrexia, a focus of infection should be sought.

The causes of a raised temperature postoperatively include:

- days 2–5: atelectasis of the lung;
- days 3–5: superficial and deep wound infection;
- day 5: chest infection, urinary tract infection and thrombophlebitis;
- >5 days: wound infection, anastomotic leakage, intracavitary collections and abscesses;
- DVTs, transfusion reactions, wound haematomas, atelectasis and drug reactions, may also cause pyrexia of non-infective origin.

Patients with a persistent pyrexia need a thorough review. Relevant investigations include full blood count, urine culture, sputum microscopy and blood cultures (Summary box 21.8).

Summary box 21.8

Fever

- A very common problem postoperatively
- Consider problems in the lung, urine and wound

Prophylaxis against infection

In patients who have had foreign material inserted during the operation, including a hip or knee prosthesis in orthopaedic surgery or aortic valves in cardiovascular surgery, up to three doses of a prophylactic antibiotic should be administered, usually one dose 30 minutes before 'knife to skin' and two postoperatively. Bacteria can be incorporated into the biofilm that forms on the surface of the implant, where they are protected from antibiotics and from the natural defences of the body; prophylactic antibiotics appear to reduce the risk of any contamination developing into infection by destroying bacteria before they are incorporated into the biofilm.

Pressure sores

These occur as a result of friction or persisting pressure on soft tissues. They particularly affect the pressure points of a recumbent patient, including the sacrum, greater trochanter and heels. Risk factors are poor nutritional status, dehydration and lack of mobility and also include the use of a nerve block anaesthesia technique. Early mobilisation prevents pressure sores, while those who are unable to turn in bed should be turned every 30 minutes to prevent pressure sores from developing. High-risk patients may be nursed on an air filter mattress, which automatically relieves the pressure areas (Summary box 21.9).

Summary box 21.9

Preventing pressure sores

- Recognise patients at risk
- Address nutritional status
- Keep patients mobile or regularly turned if bed-bound

Confusional state

Acute confusional states can occur on recovery from anaesthesia (postoperative delirium (POD)) or a few days after surgery. The overall incidence of POD is 5–15 per cent, but is higher in the elderly with hip fractures and is associated with increased morbidity and mortality (Table 21.3).

Table 21.3 Causes of confusion.

	Cause
Renal	Renal failure/uraemia
	Hyponatraemia and electrolyte disorders
	Urinary tract infection
	Urinary retention
Respiratory	Hypoxia, e.g. chest infection
	Atelectasis
Cardiovascular	Pulmonary embolism
	Dehydration
	Septic shock
	Myocardial infarction
	Chronic heart failure
Drugs	Arrhythmia
	Opiates, including heroin
	Hypnotics
	Cocaine
	Alcohol withdrawal
Neurological	Hypoglycaemia
	Epilepsy
	Encephalopathy
	Head injury
	Cerebrovascular accident
Idiopathic (rare)	Hypothyroidism
	Hyperthyroidism
	Addison's disease

Confusion may present as anxiety, incoherent speech, clouding of consciousness or destructive behaviour, e.g. pulling out of cannulae.

Risk factors for POD include pre-existing cognitive impairment (dementia), use of narcotics, benzodiazepines, alcohol (and withdrawal from it), severe illness, renal impairment and depression. Precipitating factors include use of physical restraints, addition of new medications, electrolyte and fluid abnormalities, intraoperative blood loss and admission to an intensive care unit.

Treating the underlying medical problems, involving relatives or friends who are known to the patient, and pain control will all be valuable. As a last option, haloperidol may be given in titrating doses.

Drains

Drains are used to prevent accumulation of blood, serosanguinous or purulent fluid or to allow the early diagnosis of a leaking surgical anastomosis. In clean surgery, such as joint replacement, blood collected in drains can be transfused back into the patient

provided that an adequate volume (>150 mL) is collected rapidly (<12 hours) and that a specifically designed drain and filter system is used.

The use of surgical drains has decreased in recent years as the evidence for their benefits has been questioned. They can result in complications, such as trauma to surrounding tissues, and act as a conduit for infection. The quantity and character of drain fluid can be used to identify any abdominal complication, such as fluid leakage (e.g. bile or pancreatic fluid) or bleeding. This lost fluid should be replaced with additional intravenous fluids with the same electrolyte contents. Continued loss of blood through the drain should be investigated for the source.

Drains should be removed as soon as possible and certainly once the drainage has stopped or become less than 25 mL/day.

Wound care

Within hours of the wound being closed, the dead space fills up with an inflammatory exudate. Within 48 hours of closure, a layer of epidermal cells from the wound edge bridges the gap. So, sterile dressings applied in theatre should not be removed before this time.

Wounds should be inspected only if there is any concern about their condition or the dressing needs changing. Inspection of the wound should be performed under sterile conditions. If the wound looks inflamed, a wound swab may need to be taken and sent for Gram staining and culture. Infected wounds and hematoma may need treatment with antibiotics or even a wound washout. Samples obtained at this time should be sent for bacteriology (before any antibiotics are given), any dead tissue excised and bleeding vessels identified and closed off. The wound should be packed if it is contaminated or if any nonviable tissue remains. The patient should return to theatre every 24–48 hours for further cleaning until the wound is clean enough to close.

Skin sutures or clips are usually removed between 6 and 10 days after surgery. The period can be shorter in wounds on the face or neck, and are left longer if incision has been closed under tension. If the wound is healing satisfactorily, then the patient may be allowed to shower one week after surgery. Wound healing is delayed in patients who are malnourished, or have vitamin A and C deficiency. Steroids also inhibit the adequate healing of wounds as they inhibit protein synthesis and fibroblast proliferation. Diabetes, particularly if uncontrolled, also has a deleterious effect on wound healing.

Wound dehiscence

Wound dehiscence is disruption of any or all of the layers in a wound. Dehiscence may occur in up to 3 per cent of abdominal wounds and is very distressing to the patient.

Wound dehiscence most commonly occurs from the 5th to the 8th postoperative day when the strength of the wound is at its weakest. It may herald an underlying abscess and usually presents with a serosanguinous discharge. The patient may have felt a popping sensation during straining or coughing. Most patients will need to return to the operating theatre for resuturing. In some patients, it may be appropriate to leave the wound open and treat with dressings or vacuum-assisted closure (VAC) pumps (Summary box 21.10).

Summary box 21.10**Risk factors in wound dehiscence****General**

- Malnourishment
- Diabetes
- Obesity
- Renal failure
- Jaundice
- Sepsis
- Cancer
- Treatment with steroids

Local

- Inadequate or poor closure of wound
- Poor local wound healing, e.g. because of infection, haematoma or seroma
- Increased intra-abdominal pressure, e.g. in postoperative patients suffering from chronic obstructive airway disease, during excessive coughing

Enhanced recovery

Enhanced recovery is an approach to the perioperative care of patients undergoing surgery. It is designed to speed clinical recovery of the patient, and reduce the cost and the length of stay of the patient in the hospital.

It is achieved by optimising the health of the patient before surgery and then delivering evidence-based best care in the perioperative period.

Postoperative strategies for enhanced recovery include:

- Early planned physiotherapy and mobilisation.
- Early oral hydration and nourishment.
- Good pain control using regular paracetamol with nonsteroidal anti-inflammatory drugs (NSAIDs). Epidurals and nerve blocks are managed by acute pain teams.
- Discharge planning is started before the patient is even admitted to hospital and involves support from stoma care nurses, physiotherapists and other community care workers.

Early mobilisation is encouraged to reduce the risks of DVT, urinary retention, atelectasis, pressure sores and faecal impaction. Telephone follow up is carried out to make sure that the patient is recovering well once discharged.

DISCHARGE OF PATIENTS

Patients discharged home need a 'discharge letter' detailing the postoperative plan. The discharge letter should include details of the final diagnosis, the treatment and any complications that may have occurred. There should be advice for referring the patient back to hospital and indications for readmission if specific problems do occur. The GP should be informed of the subsequent care plan including follow up, physiotherapy and other support needed. Pathology results should be included if available and the basis of these in the subsequent care plan should be described along with the prognosis if appropriate (Summary box 21.11).

Summary box 21.11**Discharge letter**

- Diagnosis
- Treatment
- Laboratory results
- Complications
- Discharge plan
- Support needed
- Follow up

Follow up in clinic

Patients should only be reviewed in clinic when a key decision on management needs to be made. The findings and the care plan agreed with the patient at the clinic appointment should be included in a letter to the patient's GP, as well as in a clear handwritten entry in the notes. This should include advice on how to recognise the onset of complications and what to do if there is concern. Patients should be discharged from clinic as soon as their GPs or they themselves can manage their care.

CHAPTER 22

Day case surgery

LEARNING OBJECTIVES

To understand:

- The concept of the day-surgery pathway
- The importance of patient selection and preoperative assessment
- Basic principles of anaesthesia for day surgery
- The spectrum of surgical procedures suitable for day surgery
- Postoperative management and discharge arrangements

DAY SURGERY PATHWAY

Day surgery offers advantages for health-care delivery around the world and so rates have steadily increased in both developed and developing countries. The increase in day surgery popularity is due to both patient preference and financial considerations. The removal of an overnight stay provides significant savings to the hospital. The original concept of day surgery was the admission and discharge of a patient for a specific procedure within the 12-hour working day. Where a patient requires an overnight admission, then the term '23-hour stay' should be used (Summary box 22.1).

Summary box 22.1

Definition of terms used in ambulatory surgery

- Outpatient surgery: not admitted to a ward facility
- Procedure room surgery: surgery not requiring full sterile theatre facilities
- Day or same-day surgery: admitted and discharged within the 12-hour day
- Overnight stay: 23-hour admission with early morning discharge
- Short-stay surgery: admission of up to 72 hours

Day surgery is a patient pathway, not a surgical procedure and extends from first patient contact to final discharge (Figure 22.1). Success in day surgery requires each component of the pathway to be safe and efficient and to be performed in sequence. Unplanned overnight admissions are minimised by ensuring that:

- the patient is informed and fit for the procedure;
- the procedure itself is achievable as a day case; and
- the home environment can support a postoperative patient.

SELECTION CRITERIA

Stand-alone day surgery facilities can safely perform minor and intermediate procedures, but if they lack overnight beds then the surgery undertaken and the selection criteria will need to be conservative to minimise the risk of unplanned overnight admissions requiring transfer of the patient to the parent hospital. Advanced day surgery procedures with an increased likelihood of an unplanned admission are best performed where overnight beds are available. Procedures which carry an increased intraoperative risk of complications and operations on more challenging patients are best managed in a hospital-integrated unit with the immediate availability of support services.

Figure 22.1 Day-surgery pathway.

Medical criteria

Age

There is no upper age limit. Healthy patient physiological status is a better determinant of day surgery success.

Comorbidity

Units traditionally use the American Society of Anaesthesiologists (ASA) classification which is a crude evaluation of chronic health (Table 22.1). Stand-alone units often confine their criteria to ASA I and II patients, while ASA III patients are more suitable for hospital-integrated units. Patients with significant respiratory or cardiovascular disease should be reviewed by an anaesthetist before being accepted for day surgery. Historically many patients who are fit but hypertensive have been incorrectly excluded from day surgery. Current published evidence does not support cancellation when blood pressure is below 180/110.

Obesity

The body mass index (BMI) is calculated as weight in kilograms divided by the square of height in metres (kg/m²) and obesity is defined as a BMI >30 (Figure 22.2). Traditional guidelines are conservative about obesity due to fears of intra- and postoperative complications. Although there is an increased incidence of

Table 22.1 The American Society of Anaesthesiologists Physical Status Classification.

Classification	
1	A normal healthy patient
2	A patient with mild systemic disease
3	A patient with severe systemic disease
4	A patient with severe systemic disease that is a constant threat to life
5	A moribund patient who is not expected to survive without the operation

Reproduced with permission from: American Society of Anaesthesiologists (1963).

non-serious respiratory complications intraoperatively and in the immediate postoperative recovery period, the course of these patients is otherwise uneventful. They should, however, be managed by experienced medical and nursing staff. Hypertension, congestive cardiac failure and sleep apnoea are all more common in patients with morbid obesity, but in selected and optimised patients, a BMI up to 40 for surface procedures and 38 for laparoscopic procedures are acceptable in advanced units.

Figure 22.2 Body mass index calculator.

Adolphe Quetelet, 1796–1874, Belgian mathematician, astronomer and statistician who was the pioneer in establishing the criteria of obesity that became known as the Quetelet Index. In 1972 Ancel Keys (1904–2004), an American Scientist from the University of Minnesota and an expert on human nutrition, public health and epidemiology, named it the Body Mass Index.

Social criteria

Safe and comfortable discharge home requires the patient to be accompanied by a responsible and physically able adult to remain with them overnight. Home circumstances require appropriate toilet facilities and the means of contacting the hospital should complications occur. A journey time to home of an hour or less is advocated, but the comfort of the journey rather than the time involved is more relevant.

Surgical criteria

Patients undergoing procedures up to 2 hours in duration can safely undergo day surgery with modern anaesthetic techniques. The degree of surgical trauma is an important determinant of success therefore entry to abdominal and thoracic cavities should be confined to minimal access techniques. Whatever the procedure, the main requirement is that there is suitable control of pain and the ability to drink and eat in a reasonable timescale (Summary box 22.2).

Summary box 22.2

Selection criteria for day surgery

- Medical: use physiological rather than chronological age
ASA status over II requires careful review
Provided that the BMI is under 40, this alone is not a contraindication
- Social: a responsible adult carer must be available for first 24 hours
home conditions need to be suitable
ability to contact hospital in an emergency
- Surgical: operations up to 2 hours
recognised day-surgery procedures
ability to eat and drink within reasonable timescale.

PREOPERATIVE ASSESSMENT

The evaluation and optimisation of a patient's fitness for surgery is known as preoperative assessment and is best performed by a specialist nursing team with support from an anaesthetist with an interest in day surgery. The assessment should be performed early in the pathway to allow time to optimise health problems before surgery. The consultation consists of a basic health screen to include the measurement of BMI, blood pressure and an assessment of past medical history with current medication recorded. Appropriate investigations are performed to ensure the patient is fit for surgery. The patient and/or their carer should be given verbal and written information regarding admission, operation and discharge (Summary box 22.3).

Summary box 22.3

Preoperative assessment

- On all day-surgery patients
- Early in the patient pathway
- By a specialist nursing team with anaesthetic support

PERIOPERATIVE MANAGEMENT

Scheduling

With dedicated day surgery lists, major procedures should be scheduled early on morning lists to allow maximum recovery time. When the list is in the afternoon, the allocation of local or regional anaesthetic cases later in the day helps reduce unplanned overnight admissions following general anaesthesia. When mixed lists of day and inpatient cases are planned, then day cases should go first. Where complex inpatient surgery is undertaken, the mixing of day and inpatient cases is not advisable. The complex case may be inappropriately delayed if the day case is scheduled first and conversely if the day-case patient is scheduled later, it may result in cancellation or an unplanned overnight admission for the day case.

Anaesthesia and analgesia

Successful day-surgery anaesthesia requires a multimodal approach to analgesia, while ensuring patients are given optimal dosages of anaesthetic agent. The agents used matter less than the skill of the person providing anaesthesia.

Multimodal analgesia starts in the preoperative period and unless contraindicated, patients should receive full oral doses of paracetamol and a nonsteroidal anti-inflammatory drug (NSAID), such as ibuprofen. Intraoperative anaesthesia can be maintained by any of the traditional inhalational agents. TIVA (total intravenous anaesthesia) techniques using propofol are also popular and offer the advantage of reduced postoperative nausea and vomiting (PONV). The use of intraoperative analgesia will depend on the procedure being performed. When available, the anaesthetist should use short-acting opioids (fentanyl, alfentanil). Careful use of these agents can minimise the incidence of PONV. Where the choice is limited to morphine, this should be used in small doses (under 0.1 mg/kg) to minimise sedation and PONV. Wherever possible, a long-acting local anaesthetic agent, such as bupivacaine, should be injected into wounds by the surgeon.

Pain levels should be routinely assessed in the postoperative recovery area. Further doses of paracetamol, fentanyl or low doses of morphine can be used to ensure that patients are comfortable prior to return to the ward (Summary box 22.4).

Summary box 22.4

Optimal analgesia and anaesthesia

- Multimodal analgesia with paracetamol and nonsteroidal anti-inflammatory drug (NSAID) (if not contraindicated) should be given preoperatively
- Use long-acting local anaesthetic infiltration of the surgical wound
- Careful dosing of inhalational or intravenous agents should be used to maintain anaesthesia
- Avoid long-acting opioids, such as morphine, to reduce the incidence of sedation and postoperative nausea and vomiting (PONV)

Postoperative complications

The range of postoperative complications is no different from normal surgery. However, the fact that the patient will be

discharged home within a few hours of surgery requires proactive monitoring after surgery. Haemorrhage is dealt with later in the chapter. Nausea and vomiting is not uncommon and should be managed actively to maximise successful discharge (Figure 22.3). Inadequate recovery from anaesthesia, uncontrolled nausea and vomiting and inadequate pain control are the most common anaesthetic related causes of postoperative admission.

Figure 22.3 Active management of postoperative nausea and vomiting (PONV).

SURGERY

For some surgical specialties, over 90 per cent of their elective workload can be achieved in day surgery. As a result, teaching and training now routinely occurs on day-surgery lists, but requires structure and close supervision. As the spectrum of procedures has increased and become more challenging, there has been a culture change among surgeons to increase their involvement in day surgery. This is important because safe and efficient day surgery demands the competence and skill of an experienced surgeon. Some surgeons have concerns regarding patient safety after discharge. The risk of postoperative haemorrhage occurring once the patient has returned home following tonsillectomy or laparoscopic surgery is often stated as a major reason to keep the patient in hospital overnight. Reactionary haemorrhage commonly occurs in the first 4–6 hours after surgery, but the patient is unlikely to have been discharged home within this time period. It may be caused by slippage of a ligature, displacement of blood clot, cessation of vasospasm, after coughing or increased mobility. Secondary haemorrhage is defined as occurring at least 24 hours after surgery, but usually presents several days later, as it is due to postoperative infection. Thus, even if the patient had stayed overnight, these postoperative bleeds are still likely to occur once the patient has returned home (Summary box 22.5).

Good surgical technique requires minimal tissue traction or tension and good haemostasis. In day surgery, these attributes are even more important (Summary box 22.6). The number and variety of surgical procedures performed on a day-case basis is increasing year on year. Many developments have been pioneered by individual surgeons in isolated centres and their expertise has yet to spread to mainstream surgery. Volume

procedures in general surgery where the British Association of Day Surgery considers at least 40 per cent of procedures can be performed on a day-case basis are shown in Table 22.2.

Summary box 22.5

Surgical haemorrhage

- Reactionary: occurs 4–6 hours after surgery and is caused by ligature slippage, clot displacement or cessation of vasospasm, after mobilisation or coughing
- Secondary: occurs more than 24 hours after surgery and is due to infection eroding a vessel

Summary box 22.6

Requirements for successful day surgery

- Minimal access techniques
- Good haemostasis
- Avoidance of unnecessary tissue handling or tension

Table 22.2 Volume procedures where 40 per cent or more should be performed on a day-case basis.

Surgery	
Abdominal	Excisional/treatment of anal lesions, haemorrhoidectomy, primary and recurrent inguinal/femoral herniae, laparoscopic cholecystectomy, laparoscopic fundoplication, pilonidal sinus surgery
Breast	Excision/biopsy breast lesion, sentinel node excision
Genitourinary	Laser prostatectomy, orchidectomy, circumcision, excision of hydrocoele/varicocele/epididymis
Orthopaedic	Dupuytren’s fasciectomy, carpal tunnel release, therapeutic arthroscopy of knee or shoulder, bunion operations, removal of metalwork
Vascular	Varicose vein procedures, thoracoscopic sympathectomy

Reproduced with permission from British Association of Day Surgery (2009).

DISCHARGE

The assessment of when a patient is fit for discharge is best performed by trained day-surgery nurses using strict discharge criteria (Table 22.3). While postoperative review by the surgical team is encouraged, the discharge should not be delayed by failure of their timely attendance. A suitable supply of analgesics for the management of pain should be provided. Paracetamol, NSAIDs and codeine form the basis of the drugs available in many countries.

Table 22.3 Discharge criteria.

Vital signs stable for at least 1 hour
Correct orientation as to time, place and person
Adequate pain control with supply of oral analgesia
Understands how to use oral analgesia supplied
Ability to dress and walk, where appropriate
Minimal nausea, vomiting or dizziness
Has taken oral fluids
Minimal bleeding or wound drainage
Has passed urine (if appropriate)
Has a responsible adult to take them home
Has a carer at home for the next 24 hours
Written and verbal instructions given about postoperative care
Knows when to come back for follow up (if appropriate)
Emergency contact number supplied

LEARNING OBJECTIVES

To gain an understanding of:

- The importance of time in trauma management
- How to assess a trauma problem
- How to respond to a trauma problem
- The value of planning

WHAT IS TRAUMA?

Trauma is the study of medical problems associated with physical injury. The injury is the adverse effect of a physical force upon a person. There are a variety of forces that can lead to injury, including thermal, ionising radiation and chemical. However, the force involved in most injuries is mechanical. The subject of trauma therefore centres upon the deleterious effects of kinetic energy on the human frame. In the next group of chapters we will explore trauma from a variety of perspectives related to different specialties. In this introduction, we will look at the aspects that bind the whole topic together.

THE SCALE OF THE PROBLEM

Trauma is recognised as a serious public health problem. In fact, it is the leading cause of death and disability in the first four decades of life and is the third most common cause of death overall.

Millions of people are killed or disabled by injury each year. Of the 5 million people killed as a result of injuries in 2000, approximately 1.2 million people died of road traffic injuries, 815 000 from suicide and 520 000 from homicides. In the UK, the accidental and deliberate injury standardised death rate (SDR) is 27.28 deaths over all ages per 100 000 inhabitants per year. Hundreds of thousands who survive their injuries experience long-term or permanent disabilities, time lost from work or family responsibilities, costly medical expenses, profound change in lifestyle, pain and suffering, regardless of gender, race or economic status. An injury affects more than just the injured person; it affects everyone who is involved in the injured person's life. The importance of the modern epidemic of motor vehicle accidents (MVA) to the global epidemic of violent injury cannot be overstated.

Trauma is not just related to high-energy transfer in road accidents or to violence. The elderly fall victim makes up the most common group to be admitted to hospital following injury in the UK. Fragility fractures represent an increasing load on health services. About 70 000 patients suffer a proximal femoral fracture each year in the UK. About 30 per cent of those over the age of 65 years who suffer a proximal femoral fracture will die

within a year of the incident, and most of the others will have diminished independence and mobility. It can be appreciated that this represents a huge burden on the health services and society in general.

The great majority of injuries are not life- or limb-threatening. Here the challenge is not only to treat the minor injuries, but also to differentiate between those injuries that have some important aspects and those that are genuinely straightforward. For instance, in children, one must always be alert to the potential for non-accidental injury (NAI). There is a chilling statistic that in 66 per cent of cases when children die as the result of abuse there has been some previous relevant contact with a health professional or social services. In all age groups, we need to be wary of pathological fractures; here the more important problem may not be the injury itself, but the underlying disease process (Summary box 23.1).

Summary box 23.1**Trauma: the scale of the problem**

- Trauma is the major cause of death in the young
- Fragility fractures are an increasing burden
- Look beyond the obvious in trauma management

THE MANAGEMENT OF TRAUMA

We learn how to manage trauma based on evidence, extrapolation from principle and by copying. All of our actions should have a purpose, for those based on evidence or principle this is frequently apparent. However, our actions based on mimicry and protocol may have less obvious foundations. While this may help to reduce delay when under pressure, we should also attempt to understand why we are carrying them out.

The importance of time

An identifying feature in the study of trauma is time. At time zero, the person/patient is at their normal baseline. There is then some interaction with an external force leading to injury. The

subsequent development of pathology, the response of the body by way of compensation and healing, and the external responses by health professionals all have a timeline. The timeline may be used to compare and consider the progress from time zero to other significant events or deadlines that follow.

Figure 23.1 depicts an estimate of the periods of time that may elapse from time zero to death or irretrievable damage for various injuries. It reflects the fact that some problems tend to lead to earlier death than others. An obstructed airway, a tension pneumothorax, an extradural haematoma or an ischaemic limb will all tend to progress along a characteristic timeline after the moment of initial injury if left untreated. This creates an 'imperative of time' that shapes and provides a basis for the hierarchy of our initial medical response to the injured patient. Thus, an obstructed airway will need emergency initial management at the scene of the accident. An ischaemic limb may be dealt with urgently once the patient has reached a definitive treatment centre. The ATLS (Advanced Trauma Life Support) system defines an order of priorities given by ABCD; that is airway, breathing, circulation and disability (neurology). This is founded upon this time dependence.

To this raw diagram of the time from injury to death or irretrievable damage may be added other components. These are the time to understand or assess the nature of the problem and the time to respond effectively to that which has been discovered. Each of these will take a finite length of time and this is shown schematically for a generic condition in Figure 23.2. It can be seen that in this example there is adequate time for an orderly

Figure 23.1 Estimated time from incident to death or irretrievable damage for various conditions.

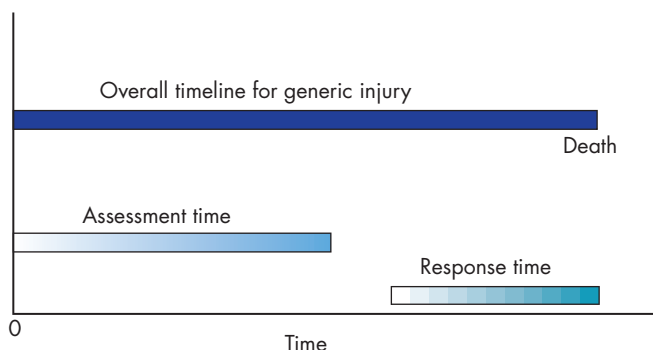

Figure 23.2 Diagrammatic representation of the relationship between assessment and response times. In this example, there is time to assess and respond effectively before death.

process of all the stages of assessment followed by a response before irretrievable damage or death.

The block of time allocated to assessment may be broken down further. Understanding and assessing the nature of the problem usually hinges on diagnosing the injury. An injury may be found by careful physical examination or need special investigation before it is discovered. It therefore becomes obvious at different points on its timeline. An example is an evolving extradural haematoma: the initial skull fracture may be visible on radiography or computed tomography (CT); as the haematoma develops it will first be visible on CT; later, it will be suspected on careful clinical examination; and, finally, it will become clinically very obvious. This is represented in Figure 23.3a.

The next feature to add to the timeline is the response time. Once an obstructed airway is identified, the response time to carry out a life-saving simple airway manoeuvre may be a matter of seconds. Thus, even at the stage when the diagnosis is clinically obvious, there may still be time to resolve the problem before irretrievable damage occurs. However, when dealing with an extradural haemorrhage, the average response time from identification of the problem to surgical resolution may be measured in hours. This may seem an unduly long time, but bringing the patient to an operating theatre with a neurosurgeon takes time to arrange, as seen in Figure 23.3b. If we now combine the various features of a timeline for the single condition of extradural haematoma, difficulties become apparent. In Figure 23.3c, it is seen that if the response is only initiated once the diagnosis has become obvious, then there may be insufficient time left to resolve the problem before death intervenes. This seems to suggest that we need to initiate a response to a problem before we are sure of its existence if we are to save the patient's life. This apparent paradox will be explored further. However, for the moment it can be likened to the need to identify a cancer at an early stage to give the best chance of successful treatment. A common approach to such a problem is to screen the at-risk population, and the same principle applies in the management of trauma.

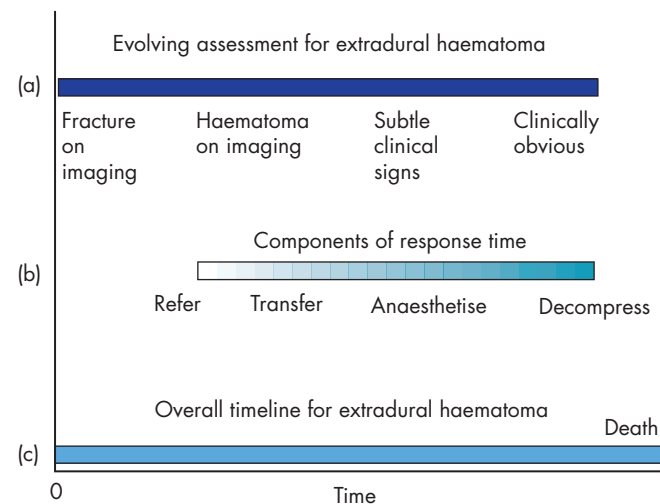

Figure 23.3 Diagrammatic representation of the relationship between assessment and response times for extradural haematoma. (a) The stages of assessment; (b) the components of the response and (c) the overall time from incident to death. It can be seen that relying on obvious clinical signs gives insufficient time to respond effectively.

As we will see, much of the medical preparation and planning related to trauma is aimed at reducing the diagnosis time and the response time so that they will fit into the time available before death or irretrievable damage. To revise the meanings of these terms, the diagnosis time is the time between injury and recognition of the problem and the response time is the time that elapses between identifying the problem and effective intervention being completed. We can reduce these times by using a practised, protocol-driven approach to the initial stages of the management of an injured patient. We must still think, but it does mean that we can have a pre-existing structure upon which to build those thought processes. This allows us to move forward more rapidly. This structured initial approach allows for more straightforward teamwork, standardisation of the equipment required and confidence in a difficult situation.

The pressure of time determines the manner in which we deal with the multiply-injured patient. The normal sequence of history, examination, provisional diagnosis, special investigations, diagnosis and management plan is not appropriate under this pressure. When dealing with the multiply-injured, a quite different approach is needed. As will be seen, the primary survey used in ATLS combines the identification of life-threatening problems with their management. It has evolved to improve the chances of the necessary actions being taken within the time available. The system has to allow for diagnosis to be made and response completed within the timeline for the injuries sustained. Increasingly, special investigations are being lavished on the multiply-injured patient with the aim of trying to reduce further the delay to accurate diagnosis.

The model of a timeline need not be restricted to the multiply-injured patient. The role of time when dealing with an elderly person who has been injured is still present, but is frequently ignored. In these cases, there may be hidden urgent issues. Thus, when dealing with the elderly, we too readily label a patient with the most obvious problem (such as a hip fracture) without performing the vital initial physiological triage. The patient may often have a primary cardiac, respiratory or neurological problem that has resulted in a fall and the response to this may be the most urgent issue. Therefore, the timeline is not only relevant to the acute and obviously urgent clinical issues. As noted at the beginning of this chapter, a timeline may be used to compare and consider the progress from time zero to other significant events or deadlines that follow. In this case, the response time to arrange a discharge from hospital for the elderly patient may be critically protracted. Figure 23.4 demonstrates that, with such a long response time, to allow for discharge at the appropriate clinical time the social planning needs to commence almost at the time of admission. This is well before it would seem clinically reasonable, but to achieve an efficient system, it can be seen to be necessary. This approach allows an emergency unit to get as close as is possible to the practice of an effective elective unit where discharge plans are made before the patient is admitted.

Time also plays a part in how we deal with more minor injuries. There is a need and expectation that these patients will be dealt with rapidly; however, there is then a danger, especially with inexperienced doctors, that corners will be cut and problems missed. Focusing on the important issues without risking missing problems is a difficult skill. Although not all patients will be seen by more than one doctor, another health professional, usually a nurse, will see them and their observations should not be ignored. A common safety net for the front-line medical

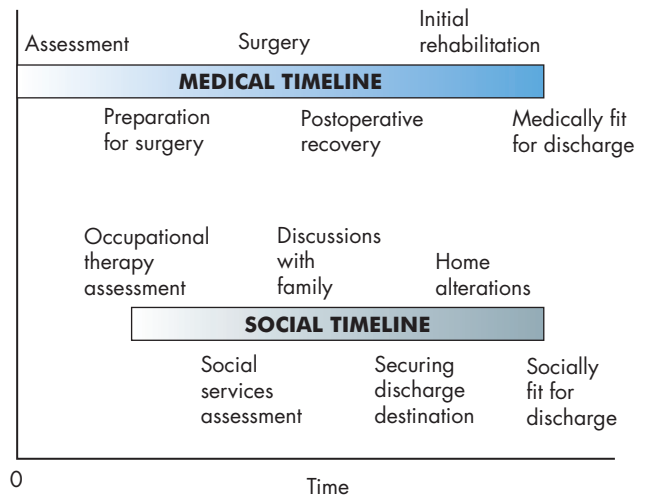

Figure 23.4 Social and medical timelines for an elderly patient with a proximal femoral fracture. Discharge can only occur when both are complete.

staff is that all x-rays of patients discharged are independently reviewed by a radiologist. Should their findings differ from those in the clinical record, the patient can be recalled and reassessed.

Timelines reveal that things change. As a consequence, reassessment can be of vital importance. An observation, an x-ray or a blood test are only snapshots in time. Repeated observation will reveal trends that may make a diagnosis more straightforward. Modern monitoring allows this continuing vigilance to be carried out more straightforwardly. Graphical recording of results in a single place makes trends easier to follow.

Although the pressure and relevance of time shapes our response to the injured, it should not be allowed to degrade it (Summary box 23.2).

Summary box 23.2

The importance of time

- Time pressure shapes our management of trauma
- There is a finite time to assess
- There is a finite time to respond
- For success, these must fit into the available time before irretrievable damage or death

ASSESSMENT AND RESPONSE

The breakdown of our approach to the injured into two components of assessment and response has been introduced. Although the two concepts overlap and intertwine, it is helpful to explore them separately.

The assessment of trauma

At time zero, a person in their baseline condition comes together with an external force to produce injury. Understanding this relationship between the patient, the mechanism of injury and the injury produced is the key to understanding the problem that has to be solved. This is helpful both when making a diagnosis

and treatment plan for an individual, and also for structuring the thinking of the management of trauma in general. The relationship can be expressed simply as: mechanism + patient = injury.

The nature of these components may be quite obvious (overt) or in some way hidden (covert). We need to convert everything to the overt. We can only treat what we have found; we can only resolve the problems that we have identified.

A tidy relationship between the mechanism, the patient and the resulting injury is often obvious. A previously healthy 40-year-old man falling vertically 2 metres and landing on his feet may sustain an os calcis fracture. From this position of understanding, we can move swiftly forward to confirm and treat. In many cases, there is something more to find out or to understand.

It may be that the three variables just do not add up to form a complete picture. This failure of the relationship is not real but apparent. If the three variables do not fit together something has probably been misjudged, and the factor that is causing the failure of the clinical picture to 'add up' must be sought. It may be that some aspect of the injury has not yet been discovered, the mechanism suggested may not be genuine or there may be some aspect of the patient before the injury of which one is unaware (Summary box 23.3). To expand on this theme, we will explore how to use the available information to best effect.

Summary box 23.3

The assessment of trauma

- Use all of the information: mechanism, patient and injury
- Allow the obvious features to be a guide to the less obvious
- If the equation does not add up, look for more reasons

Mechanisms

Mechanisms may be blunt or penetrating. One of the easiest of these to understand is the incision caused by a knife. We are used to knives both at home when we eat and as surgeons when we operate. A knife has a sharp edge that may cut tissues with which it makes contact; these effects are easily appreciated because they happen in a timescale that we understand. A knife damages only what it can reach. A good history of the length of blade coupled with an entry point allows for a potential pattern of injury to be imagined and then individual components to be confirmed or excluded by examination, special investigation or wound exploration (Table 23.1).

Thus, an incisional injury over an extremity is readily evaluated as long as the relevant anatomy is known. The distal perfusion, peripheral nerve function and tendon and muscle function can all be assessed by clinical examination. However, should joint penetration be a possibility then the problem is different. Understanding the timeline is of value. The consequences of a septic arthritis are severe and if treatment is delayed until the condition is clinically obvious, then it may be too late to prevent permanent damage. Therefore, the diagnosis of joint penetration needs to be excluded by screening the at-risk group. If a large joint is involved, for example the knee, an algorithm such as that in Figure 23.5 can help identify those joints that need formal exploration. One component of this algorithm is to fill the joint until tense with sterile saline and watch whether fluid leaks through the traumatic wound. This will show whether the joint has been penetrated. If the joint has been breached, a

Table 23.1 Examples of patterns of injury.

Mechanism	Obvious features	Covert injuries
Left-sided impact from road traffic accident	Lateral compression of the pelvis Left-sided pneumothorax	Splenic rupture Extradural haematoma
Flexion distraction (lap belt)	Chance fracture of the lumbar spine Dislocated knee	Duodenal rupture Popliteal artery disruption
	Head injury	Cervical spine fracture
Electrocution	Burn on hand and collapse	Posterior dislocation of the shoulder
Dashboard impact	Knee wound	Posterior dislocation of the hip

formal procedure in an operating theatre is required. This action is now therapeutic and not exploratory.

In assessing the effects of an incisional mechanism over the torso, the first step is again to decide which structures are at risk. This may seem simple, but it is not always easy to determine the direction that a blade has entered. The anatomy can also be confusing; it is worth recalling that the abdominal contents extend higher than normally expected, up to the level of the fifth rib in expiration. A notable feature of stab injuries is that they are often eminently treatable; even cardiac injuries can be treated with a realistic chance of success if identified early (Summary box 23.4).

Penetrating injuries caused by firearms are not so easily understood as incisional injuries. A low-velocity projectile behaves

Figure 23.5 Algorithm for assessing a wound that has potentially entered a joint.

Summary box 23.4**Incisional injuries**

- Require knowledge of anatomy
- The abdominal contents extend high into the chest
- Even cardiac injuries are treatable if recognised early and treated quickly

more or less like a stabbing injury. However, as the velocity increases, the energy increases in line with $E = \frac{1}{2}mv^2$; as the amount of energy increases, the ability of the system to dissipate that introduced energy in a simple way is overcome. In the case of high-velocity projectiles, the result is not like anything we are familiar with in day-to-day life. Furthermore, these projectiles are deliberately designed to produce particular results: some are designed to kill, whereas others are designed to maim but not kill. In a military conflict, it is more disabling and demoralising to your opponent's forces if individuals do not die but consume resources in their treatment and protection.

The high-velocity bullet crushes particles of the human body in its pathway and produces lateral acceleration away from the point of impact. This motion of the tissue particles away from their original position produces a cavity. Two types of cavity are produced: (1) a permanent cavity – one that remains after the initial impact; (2) a temporary cavity – one that lasts for milliseconds, and may no longer be apparent during the physical examination of the wounded. This temporary cavitation can extend well beyond the boundaries of the apparent injury. High-speed photography shows the dramatic nature of the temporary deformation, which happens on a very rapid timescale (Figure 23.6). Awareness of this phenomenon will encourage the treating surgeon to perform an adequate exploration and, if appropriate, a more radical wound excision than would otherwise be used (Summary box 23.5).

Summary box 23.5**Firearm injuries**

- Low-velocity bullets behave like knife injuries
- High-velocity bullets cause cavitation
- The temporary cavity is large and draws in foreign materials
- The permanent cavity is smaller and gives no clue to the extent of damage

A blunt mechanism of injury can be considered as direct or indirect. A direct mechanism is when the damage occurs at or close to the site of impact. An indirect mechanism is when the damage occurs at a distant site after transmission of that force. The following examples, in which two different mechanisms leading to fracture of the ulna are considered, may help to understand this. Should an attacker strike with a strong stick, the victim may protect their head by raising their arm. The blow will then fall on the ulna. This may cause an isolated fracture of that bone generally called a 'nightstick fracture' (a nightstick being a weapon of enforcement carried by the police). This is clearly a direct injury. All of the injury is concentrated at the site of application of the force; the soft tissues may be bruised, contused or lacerated at the site. A different situation occurs if a

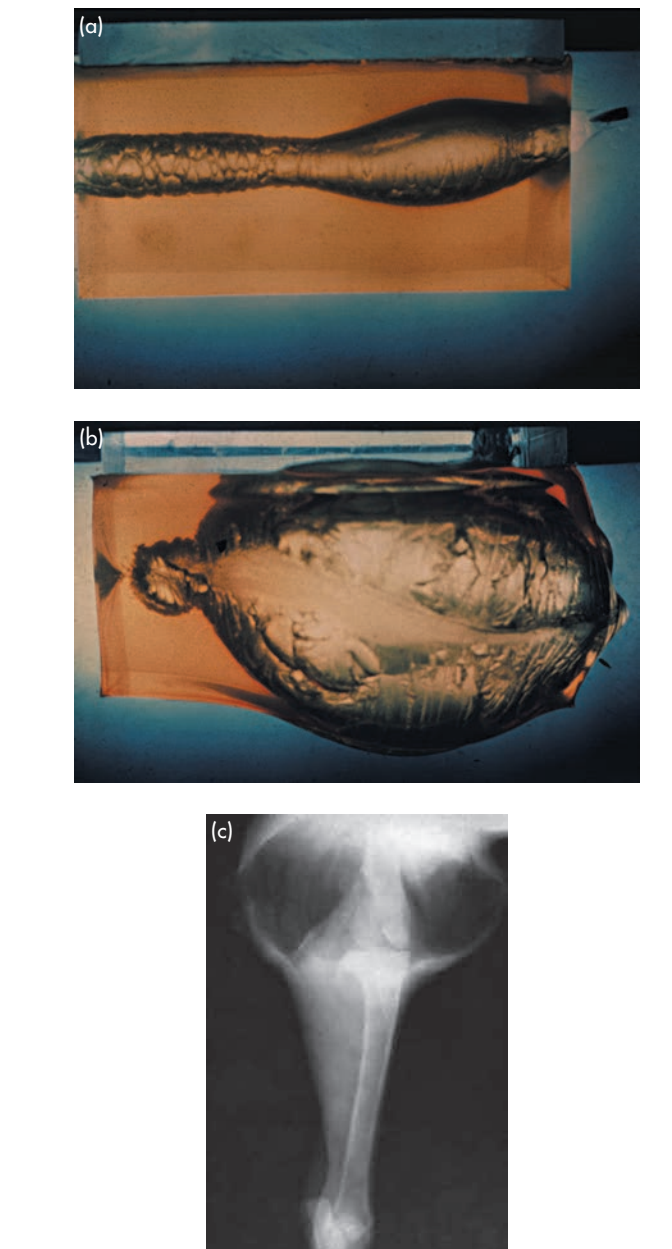

Figure 23.6 A projectile passing through a gelatin block. (a) Low energy transfer; (b) High energy transfer. (c) The effect of high energy transfer on tissues. Photographs courtesy of Professor J Ryan.

person falls on an outstretched hand. This may lead to a fracture of the ulna, but here the mechanism is indirect. The force has been transmitted through the body's tissues to a site at some distance from its application. It is unlikely that an ulnar fracture would occur in isolation in such circumstances and the 'associated injuries' should be sought. In this instance, the associated injury is often a dislocation of the radial head, the whole injury complex being called a Monteggia fracture dislocation. These injuries are demonstrated diagrammatically in Figure 23.7. The injury is often missed and the consequences are severe in the growing child. Thus, we should always evaluate the elbow fully (radiologically and clinically) in an apparently 'isolated' ulnar fracture, especially if the mechanism was indirect, usually a fall

Figure 23.7 Two examples of a fracture of the ulna. (a) A nightstick fracture from a direct blow. (b) A Monteggia fracture from an indirect force.

onto the hand. The timeline in these circumstances is not pressing. The injury can be adequately treated for some weeks after it occurs, but once the diagnosis has been missed and the wrong label applied it becomes progressively more difficult to rectify.

The energy transmission in an indirect mechanism may be via a solid structure, such as a bone, as in the examples above, or it may be via the soft tissues or fluid. Some of the resulting injuries can be quite unexpected. A compressive force to the abdomen will cause a rise in pressure that may be transmitted by the vascular system. A sudden back pressure at the heart can lead to damage to the valves. The results of direct mechanisms are easier to understand as the damaging effects are often more localised.

Even when the patient was alert before and after the event, it can be surprisingly difficult to be sure of the mechanism as it affected the injured part. The rapidity and unexpectedness of accidents means that precision in history is often hard to obtain.

Patient factors

Individuals with different physical characteristics and medical histories will respond differently to mechanical insult. In the standard history taken, a quick categorisation of a patient is normally carried out.

As we take a history, we intuitively group patients to assess the nature of their likely injuries. Children, adults and the elderly are three obvious separate groups. We anticipate different injuries in these different groups even if the mechanism is the same. A torus fracture, a Colles fracture, or fractured hip may each result from a simple fall.

Similarly knowing a patient is on anticoagulants, has osteogenesis imperfecta, has a previous total knee replacement or has known metastatic disease guides assessment.

Obvious injuries

Some injuries are so obvious that they may present before any mechanism or patient details are known. It may therefore be the presence of one overt injury that leads to the search for another; the obvious injury is being used just as a history would in other circumstances. The most obvious injuries will be those that are

visible externally. It is for this reason that there is an E at the end of ABCDE in the ATLS system: E is for exposure – look for the clues.

If a wound suggests a penetrating injury then thought should be given to the underlying structures at risk. A contusion over the knee of a driver suggests a dashboard injury. Finger-shaped bruises on a child's arms suggest non-accidental injury (NAI).

A good example of a minor but obvious injury helping in a timeline is singed facial hair. This sign is often associated with carbonaceous sputum and suggests inhalational burns. Calling an anaesthetic colleague when singed nasal hair is first noted is far better than a crash call 15 minutes later when laryngeal oedema obstructs the airway of a patient with an inhalational burn.

Exposing the patient comes readily to those dealing with trauma. The perils of not exposing the patient were demonstrated in an infamous case in the UK. A patient already in hospital for another problem had 'collapsed' by the phone within the hospital and was dealt with by the cardiac arrest team. The patient responded poorly to treatment and it was only some time later that the bullet was noticed on the chest x-ray. Following this, the bullet wound in the victim's back was found. A helpful adage borrowed from radiology is that 'unless you are very lucky you only find what you look for'.

Hidden factors

Mechanisms

Sometimes, when the normal relationship of 'mechanism + patient = injury' does not seem to hold, the hidden information may be in the mechanism. The most obvious examples are in situations in which there has been a deliberate attempt to mislead.

Conscious sensible patients reporting their own injuries will generally tell the truth; however, sometimes to protect themselves or others they may fabricate a mechanism. The risk here is that if the mechanism is incorrect, the wrong pattern of injuries may be anticipated. Thus, the man who fell from 6 metres when in some illegal activity does not help achieve an accurate diagnosis if he reports the mechanism as a twist to his ankle from a stumble. Similarly, if it is not admitted that an injury results from an assault, then no action can reasonably be taken to help protect that person from further aggression. This situation is most commonly encountered when the patient is the victim of abuse within a relationship. The patient should be given the opportunity to tell their story, but it should not always be believed.

More commonly, the problem of a hidden mechanism arises when the patient is unable to give their own history. A very young child or an elderly person is both physically and mentally vulnerable. They may have been physically abused, but be unable to report it. In these circumstances, the mechanism of injury may have been criminal. A list of some of the factors that should make one suspicious of the history and suspect that NAI has occurred is given below:

- history clearly inconsistent with the injuries sustained;
- changing history;
- aggressive behaviour of carers at interview;
- injuries of different ages;
- posterior rib injuries;
- long bone fractures in a pre-ambulatory child.

The interests of the patient are paramount and so we need to

not only identify injuries that need treatment, but also protect patients from further harm. The timeline of importance here is that which has shown that 66 per cent of children who die as the result of abuse have been in contact with a health or social work professional before the fatal episode. We have already accepted that to adequately treat an extradural haematoma, we must respond to subtle indicators in the history and physical examination to allow our response to begin early enough to be effective. An analogous situation applies with child abuse – if we ignore the early signs, we may be too late to prevent the later episode in which real harm is done. NAI is a very difficult problem to deal with. As clinicians we are more comfortable trying to help everyone; acting to police a situation does not come naturally.

In some criminal situations, the nature of any overt injuries may provide important evidence of the mechanism. Such evidence may be affected by our medical assessment and treatment. Although we should not compromise the medical management of an injured person, it is folly not to bear in mind at every stage that the victim of an assault may need good forensic evidence at some later date to convict their assailant. Indeed, the injured victim of an assault may later become a murder victim (Summary box 23.6).

Summary box 23.6

Covert mechanisms

- Patients usually tell the truth, but may not if criminal activity is involved
- Fear of abuse may prevent vulnerable patients telling the truth
- If a non-accidental injury (NAI) is suspected, you have a responsibility to take action
- Patients likely to have covert medical problems need careful checking even if their injury appears to have a simple mechanical cause

Patients

When the mechanism and the injury are obvious but inconsistent, it may be that there is something previously unknown about the patient to discover. Most commonly, this is a pre-existing pathology. Thus, a healthy adult who breaks their femur following a trivial insult may well have had a pathological weakness of the bone, such as a neoplasm. Thoughtless treatment of this as a simple fracture, without tissue diagnosis, staging, etc., may result in entirely inappropriate treatment with unnecessary loss of limb or life.

Injury in the older patient may be the manifestation of general health problems. The obvious injury may be the fractured proximal femur, the hidden patient factor may be the transient ischaemic attack or abnormal cardiac rhythm that caused the fall. Rather like the practice of the secondary survey looking for covert injury in the polytraumatised patient, a medical secondary survey is required as a screen in the elderly.

Injuries

Looking for the hidden injury when deduction has failed can follow two methods:

- 1 the look everywhere approach;
- 2 the focused exclusion approach.

1 The look everywhere approach. One of the mainstays of trauma evaluation has been the secondary survey. The essence is that once the initial life-saving manoeuvres have been completed you look everywhere for further injury. This detailed examination may take place shortly after admission, the following morning on the ward round or sometimes a week later when the patient first regains consciousness. As its name suggests, the look everywhere secondary survey comes later in the sequence of the ATLS approach. However, the emphasis placed on the timeline at the beginning of this chapter and the need for early diagnosis is leading to a different approach to the traditional 'look everywhere' one. The ATLS system has included a plain pelvic and a chest x-ray as part of the primary survey. This may confirm a clinical diagnosis, but is also a screening tool to identify injuries that may progress to a clinical problem; the response to that injury can then be initiated earlier. The threshold for using more generalised investigations such as CT scanning, ultrasound, cardiac echo and magnetic resonance imaging (MRI) to check for these covert injuries is progressively being lowered. Some emergency departments now have CT scanners in their resuscitation rooms. A head-to-pelvis CT scan is being used to replace the early plain radiographs of the chest and the pelvis. A CT scan is more sensitive and specific and its use to identify injury before the clinical signs become obvious is certain to improve patient care.

2 The focused exclusion approach. Some important injuries or conditions are for some reason missed on a surprisingly regular basis. This suggests that a normal deductive approach is not always adequate. Classic examples are scaphoid fractures, perilunate dislocations, posterior dislocations of the shoulder and tarso-metatarsal dislocations.

Therefore, if such injuries are suspected or possibly present they should be positively excluded by focused history, examination and investigation (Summary box 23.7).

Summary box 23.7

Trauma assessment

- Know the timelines for important diagnoses
- Prioritise the assessment accordingly
- Positively exclude critical diagnoses
- If required, screen at-risk patients before clinical signs are apparent

The response to trauma

Once an assessment has been made based on the factors of mechanism, patient and injury discussed above, the response must be planned and executed. At the same time, the patient will have an evolving response to injury. On the positive side, physiological compensatory and reserve mechanisms will be recruited and healing processes will be initiated. Countering this, there may be progressive pathophysiological responses, the consumption of limited resources and decompensation.

The patient's response to injury

The patient's own homeostatic mechanisms will respond to the injury and there will be physiological and pathophysiological

changes. In the light of this evolution of responses, we may alter the nature or the timing of our interventions.

A simple example is body temperature. A drop in body temperature is common after injury; this may be due to exposure, inactivity, damp, blood loss or loss of vasomotor control. The body's own thermoregulatory mechanisms may not be able to resolve the problem and so we must be prepared to support that role – body temperature should be monitored and heat loss prevented as required. It may not be possible to do this adequately in an operating theatre during a surgical procedure.

Similarly, oxygenation can be monitored and support may be given by way of increased inspired oxygen or different modes of ventilation.

The response to blood loss is not only an evolving situation for an individual patient, but our response to it also changes. The patient calls on compensatory mechanisms when blood is lost. As long as organ perfusion is adequate, low blood pressure is not a problem in its own right. The body has a finite resource of clotting factors and the injured lung does not tolerate excess fluid. The combination of these factors has led to a tendency to draw back from large-scale early fluid replacement with a crystalloid. Instead, the emphasis is placed on identifying and stopping the source of bleeding. The patient also mounts a generalised immunological response to trauma. This has an impact on their ability to tolerate surgical interventions. There is growing evidence that procedures should be timed and staged to better fit the conditions created by the patient's systemic immune response.

The medical response to injury

Initial management

The structure of ATLS is discussed in Chapter 22. Reducing the elapsed time from injury to useful intervention is critical for some patients. Preparation can aid this process. When a department is made aware of the impending arrival of a seriously injured patient, a decision needs to be made as to whether to call the 'trauma team'; this will allow a trained team of nurses and doctors to be waiting to meet the patient. While waiting, equipment is made ready, a leader is identified and each team member is given a role. Protective clothing will be needed: gloves to protect from fluids and lead aprons to protect from x-rays.

For the medical and nursing staff, the beginning of the patient's pathway can become familiar just like any routine journey and, thus, planning becomes less complex. However, if wasteful delays are to be avoided, alternatives need to be available if for some reason the routine cannot be followed. Anticipating and dealing with potential rate-limiting steps in the patient's journey will allow delays to be avoided and further reduce the response time. The component of the response that will be the rate-limiting step will depend on local, as well as general circumstances. Examples of causes of delay are obtaining a CT scan, getting the patient into an operating theatre or obtaining a necessary specialist opinion. Such steps that can potentially bring the progress of the patient to a halt need to be addressed early and sometimes in a way that may seem out of the normal sequence. This is one of the major roles of the team leader who should have an overview and be able to foresee and pre-empt problems. Whenever a system is protocol driven, someone should be in a position to take the responsibility to break protocol if required to keep the overall process flowing.

Having a practised common pathway can be disadvantageous; a patient with the wrong 'label' may go along the wrong pathway. We all have to be wary of labelling. Should two patients with identical histories and injuries arrive in an emergency department with one on a spine board and the other in a chair, the former will be treated as if more severely injured when in fact that may not be the case. We must make our own judgements on reasonable evidence and not just rely on the labels (in this case, the cervical collars) applied by others.

Labelling is most frequently a dangerous problem in the elderly. A patient with an obviously short externally rotated leg may be quickly given the label 'NOF' (fracture neck of femur). There are a number of problems with this practice. The focus is now on the orthopaedic label rather than the whole patient. The incorrect label may mask the fact that the patient could be dying. The patient may have fallen as a consequence of a cardiac arrhythmia or other comorbidity; the early labelling may therefore send the patient off on entirely the wrong pathway. All vulnerable patients should have a physiological triage to avoid such problems. This means assessing the airway, respiratory rate, blood pressure, pulse rate and consciousness. All of these assessments are more important, even in the elderly, than the presence of a fractured hip.

Beyond the first hour

The primary survey of ATLS encourages the identification and treatment of life-threatening problems. Once these have been addressed, there may be other problems that require intervention. The timing and order of these interventions is a matter of judgement. There has been an evolution in the approach to the management of polytrauma. It has been variously said that a patient may be 'too sick to operate on' or that they may be 'too sick not to operate on'. The work of Bone in particular has promoted the concept of early definitive stabilisation of long bone fractures to allow better control of the pathophysiology of trauma. Others have highlighted the need in some circumstances for limited early intervention, sometimes called 'damage control surgery'. This is followed by definitive treatment when the patient is better able to tolerate it. In orthopaedic trauma, the debate has focused on whether long bone fractures should be fixed temporarily or definitively. In general surgery, the question is whether the abdomen should be definitively treated or packed. Any patient needing a sequence of interventions, e.g. laparotomy, femoral nailing, tibial nailing, should have the most important done first. Thus, if there needs to be a break in the procedures for any reason, the most important interventions will have been completed. As each component of a sequence of procedures nears its end, a decision needs to be made whether it is safe or appropriate to proceed to the next stage. Monitoring of core temperature, coagulation, base excess, etc., will allow this decision to be made on rational grounds. When necessary the patient can then be transferred to the more controlled environment of an intensive care unit and return for definitive surgery when physiologically and immunologically better able to tolerate it; this may be hours or days later.

A useful adjunct is to record the treatment plan on a whiteboard in the operating theatre. This informs others of the intended pathway of treatment so that preparations can be made. An example of such a tactic is shown in Figure 23.8. Note the alternative pathway that exists should the patient's general condition require a shorter procedure, when the femur

can be temporarily stabilised with an external fixator rather than definitively fixed with a nail.

LOCAL PROTOCOLS AND GUIDELINES

A general guideline, such as ATLS, deals with some aspects of patient management and is used in many institutions. However, hospitals generally have individual policies to guide or direct decision making in smaller areas of practice. Examples are prophylaxis against infection and thromboembolism, the use of steroids in spinal injury and clearance of the cervical spine. These represent the efforts of individuals within an institution to plan for common and foreseeable circumstances. These protocols allow for easier and quicker decision making. Their application should protect the patient and, in an increasingly litigious world, the doctor as well.

'Clearing' of the spine is a practice that has particular relevance to trauma. The early policy for managing the spine in polytrauma patients is straightforward; it can be summarised as 'suspect and protect'. This approach is widely employed, and so very many patients have their spine protected. However, this is a precautionary approach and at some stage one has to have a strategy for discontinuing protection, or 'clearing' the spine in those patients in whom protection is not required. In the event that it is not possible to exclude spinal injury on clinical grounds, the managing clinicians may request clearance on radiological grounds. An example of such a policy for clearing the spine is given in Table 23.2.

Record-keeping for the injured patient is both important and difficult. It is often said that trends in a patient's condition are more important than isolated observations. Because an injured patient may be cared for by a large number of individuals, trends can only become apparent by reference to the sequential recorded notes. If each individual clinician records their

observations in an 'individual' manner, it becomes very difficult to identify trends. Adoption of the Glasgow Coma Scale to monitor the level of consciousness demonstrates the advantage of using a consistent system of recording observations. Such sequential observations, especially when displayed on a single chart, demonstrate trends. The clinical evolution of a problem, such as raised intracranial pressure secondary to an extradural haematoma is then easier to identify (Summary box 23.8).

Summary box 23.8

The response to trauma

- Guidelines and protocols speed and streamline management
- Pre-empt time-limiting steps to avoid delay
- Respond to the evolving condition of the patient
- Use charts to plot trends

Table 23.2 An example of a policy for clearing the spine in the obtunded patient.

Cervical spine	Fine-quality computed tomography (CT) scans of C0–T4, reformatted and assessed in the axial, sagittal and coronal planes Powers ratio to assess the atlanto-occipital junction
Thoracolumbar spine (T4 distally)	Either good-quality anteroposterior and lateral plain films or CT scans reformatted and assessed in the anteroposterior, lateral and axial planes

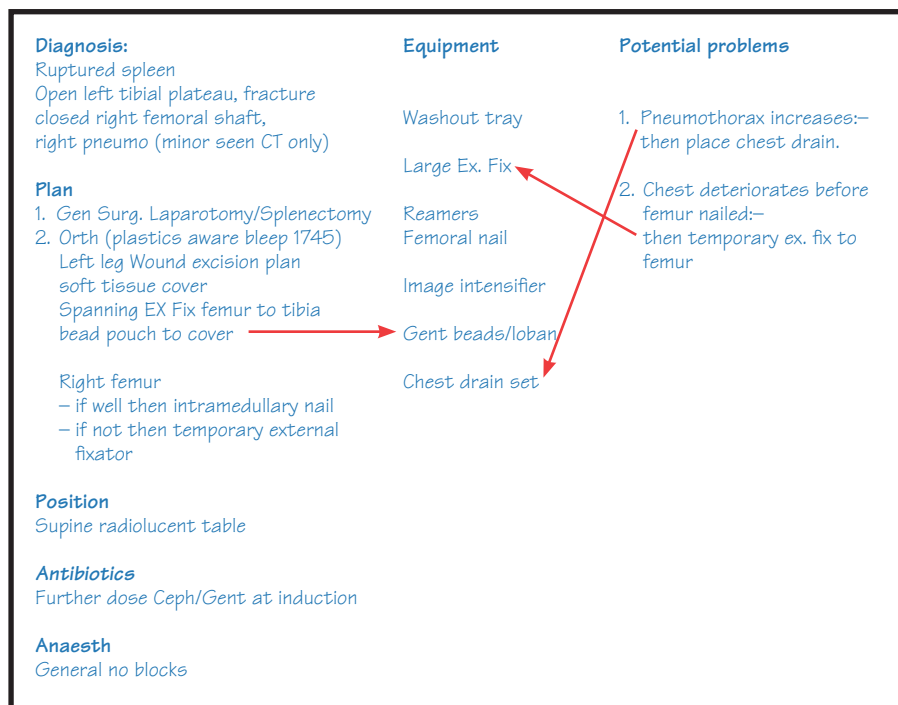

Figure 23.8 An example of a surgical tactic on a whiteboard in the operating theatre.

Planning an individual operation

The central part of a surgeon’s work is operating. Dealing with injuries is not repetitive and so thought and planning are required. Even when an individual surgeon is involved in performing the surgery, care is delivered as part of a team. It is good practice to think through the plan for the operating theatre. Mental rehearsal of a procedure may allow potential hazards to be predicted and avoided. For example,

- As the procedure is planned, it may become apparent that the proposed surgical approach will not allow the access required. In a whiteboard exercise, this can readily be altered. This cannot be done so easily if the first time this problem is appreciated is after the skin has been cut.
- It may be decided in planning that another surgeon is better suited to perform a particular procedure.

The use of the whiteboard in theatre, discussed earlier in the context of multiple injuries, is equally applicable for the isolated injury. An example of a surgical tactic for a segmental tibial fracture is given in Figure 23.9. This not only helps the surgeon,

but also informs others. The position of the patient, the surgical approach, position of the image intensifier, method of fracture reduction and instruments required, and method of fixation and implants required are all noted. Theatre staff, anaesthetic staff and radiographers can all see what is intended and it can also act as a teaching aid. A trainee may be asked to complete the whiteboard plan; they then have to commit to a plan of action and not just drift along. An important addition to the planned progress of the procedure is a list of potential problems or hazards. The strategies that will be used to deal with these problems should they arise can then be considered and prepared for (Summary box 23.9).

Summary box 23.9

Planning an individual operation

- Plan procedures before performing them
- Commit a plan to paper
- Share the surgical plan by use of a whiteboard

(a)

Diagnosis	Equipment	Problems/solutions
Open segmental fracture left tibia		
Procedure		
– Excise wound with plastics	– Radiolucent table	– Segment viable but too narrow to nail/proceed to bridge plate or ex. fix depending on soft tissue
– Plan soft tissue cover	– Tourniquet (during wound excision)	– Segment non-viable/remove segment place temp ex. fix with view to subsequent Ilizarov transport
– Secure nail entry point	– Soft tissue tray	– On passing nail malalignment of proximal fragment/remove nail and place blocking screw
– Ream segment through traumatic wound	– Washout tray	
– Statically lock nail	9 litres washout	
– Dress wound with a bead pouch	– Reamers	
– Continue antibiotics until definitive soft-tissue cover	– Cannulated tibial IM nail	
	In reserve	
	external fixator/long plates	

Figure 23.9 (a) Theatre whiteboard with surgical tactic and (b) radiograph for a complex grade IIIB open segmental tibial fracture. One of the foreseen problems has occurred as the proximal fragment is malreduced (c). The nail was removed and an anteroposterior blocking screw was placed (highlighted) (d and e). The fracture is then well reduced.

The response to the mechanism of injury (injury prevention)

When assessing the 'mechanism + patient = injury' relationship, it is easy for the doctor to focus on managing the injury; however, the mechanism of injury can also be addressed, that is we should aim to prevent rather than just treat injury.

When a mechanism of injury becomes particularly prevalent or has serious consequences, it is prudent to take steps to either remove the mechanism or reduce the consequences.

Accidents occur in a variety of places: the home, the workplace and the roads are the most common. The strategy and motivation for prevention varies from place to place. Within the workplace there is legislation to protect employees and a tendency for an injured employee to sue the employer. Thus, although some work environments are naturally dangerous, many advances in safety have been made. Within the home, legislation has little effect on behaviour. The safety of the structure of a home may be influenced by building regulations, but the thrust is on education of the individual. It is difficult to educate adults to behave more safely and so accidents in the home remain very common. Road safety is a contentious issue. The safe management of the kinetic energy of travel would seem to be a straightforward physical problem. Great advances have been made in the technology of motor vehicles to protect drivers. Restricting speed, separating vehicles travelling in different directions and segregating motor vehicles from vulnerable road users, such as pedestrians, are not popular measures (Summary box 23.10).

Summary box 23.10

Response to the mechanism of injury

- The saying that 'prevention is better than cure' is true
- Legislation and education are required
- Prevent further abuse by responding to the initial clues

The response to patient factors

Another approach to injury prevention is to alter the patient. This particularly applies to the epidemic of injuries in the elderly. Falls are the most common mechanism of injury, so one can try to address the cause or the effects of falls. Fall prevention clinics are now common. The at-risk patients are assessed and remediable causes of falls are addressed. Postural hypotension, transient ischaemic attacks and arrhythmias can be identified and treated.

Elderly people will continue to fall, so we can try to minimise the effect of the fall. Schemes, such as using hip protector pads to cushion a fall, have been tried with limited success. The area most likely to expand and give results is that of strengthening the skeleton. Identifying those at risk of osteoporosis, screening them and then treating appropriately offers a hope of reducing the incidence of low energy fractures. There was initial scepticism about the expense of such treatments and the potentially huge number of people who would require them. It is now accepted that treatment targeted appropriately will be cost-effective by reducing later fractures with the consequent costs of hospitalisation, morbidity and mortality.

Another of the patient factors discussed earlier is when

injury occurs in pathological tissues, the common example being a fracture of a bone with a neoplastic deposit. This should influence management in one of two ways. When there is a doubt as to whether the tumour is a primary or secondary, it is important to think before treatment. Injudicious operative management of a fracture associated with a primary deposit may prejudice proper tumour management; when the situation allows, a proper opinion should be obtained. When dealing with obvious secondary deposits, the situation is quite different. Aggressive surgical management is often justified to allow an early return to function. A patient with a limited life expectancy should not spend long periods of time rehabilitating (Summary box 23.11).

Summary box 23.11

Response to patient factors

- Pre-empt injury with the use of fall prevention clinics
- Carry out targeted osteoporosis treatment
- Do not treat thoughtlessly an injury that is possibly secondary to a primary neoplasm

CONCLUSION

Trauma is usually the adverse consequence of a mechanical force on a patient. The prime importance of time in trauma care needs to be appreciated. At time zero, there is a relationship between the mechanism, the patient and the injury. The components of this relationship should fit together in a rational manner. When this rational fit is not apparent, great care should be taken to look for hidden injuries, pre-existing pathology or some deliberate deception in the given history.

There is a timeline that progresses from the moment of injury. Prompt understanding of the problems is key in allowing an early reaction. It may not be possible to wait for overt clinical signs and so diagnoses should be positively sought and in some circumstances patients screened. There is a minimum response time to initiate and complete the interventions to deal with the problems. Preparation can reduce this response time. Knowledge of realistic response times is important, because only then does the clinician know the real urgency of initiating action.

When presented with an injured patient, the early management is largely protocol driven. As more details become known and the patient moves towards definitive care, a more individual plan is made. This plan coordinates the different specialties and should be flexible to allow for evolving pathology. Someone should be responsible for the patient.

Trauma does not just consist of care of the young injured. Increasingly, the injured patient will be elderly. The team involved needs to reflect the needs of these elderly patients.

Trauma need not only be addressed by tackling the injury itself. Preventative measures should be employed when particular mechanisms can be identified as being common or important causes of injury. For example, prophylactic measures may reduce the propensity for individuals to fall or reduce the consequences of those falls when they occur.

The following chapters in this section will look further at these principles as applied to specific regions or surgical disciplines (Summary box 23.12).

Summary box 23.12**Conclusion**

- The management of trauma is dependent upon time
- Multiple specialties may be involved, but do not lose sight of the overall problem
- Planning increases the chances of success

CHAPTER 24

Early assessment and management of trauma

LEARNING OBJECTIVES

To identify:

- The sequence of priorities in the early assessment of the injured patient

To learn:

- The principle of triage in immediate management of the injured patient
- The concepts of injury recognition prediction based on the mechanism and energy of injury

To apply:

- The principles of primary and secondary surveys in the assessment and management of trauma

- Techniques for the initial resuscitative and definitive care aspects of trauma

To be able to perform:

- The necessary protocols to allow early stabilization of the patient leading on to definitive care

To recognize:

- Patients whose management should differ from the normal

EPIDEMIOLOGY

Trauma is the most common cause of death between the ages of one and 44 years worldwide. By 2020, it is estimated that more than 10 per cent of people will die from trauma. In addition to mortality, injuries have the potential to cause many other long-term health problems, with serious consequences for individuals, families, communities and health-care systems. Subsequently, this represents a significant drain on resources. The economic impact of trauma and injury is huge globally, with some figures quoted in the region of \$500 billion annually.

INTRODUCTION

Much effort has gone into trying to improve trauma care, with the most recent in the UK being the introduction of specialist regional 'level one' trauma centres, where all the required facilities and subspecialties are available on site to deal with multiply-injured patients.

It is the initial assessment that is probably the most important factor in the subsequent outcome of the trauma patient, as it is at this stage that a subsequent care pathway and protocol is formed for definitive treatment.

The Advanced Trauma Life Support (ATLS) principles were introduced into practice in the late 1970s, and have since revolutionised the management of trauma (Summary box 24.1).

Once the attending clinician is versed in the structure and protocol of the ATLS philosophy, it becomes very easy to apply this to any trauma event, regardless of the nature and severity of the injuries.

Summary box 24.1

The steps in the Advanced Trauma Life Support (ATLS) philosophy

- Primary survey with simultaneous resuscitation: identify and treat what is killing the patient
- Secondary survey: proceed to identify all other injuries
- Definitive care: develop a definitive management plan

MECHANISMS OF TRAUMA

Trauma can be classified in type by causation and by effect (see Table 24.1).

Table 24.1 Types of injury.

Blunt, e.g. car bonnet
Penetrating, e.g. knife
Blast, e.g. bomb
Crush, e.g. building collapse
Thermal

Blunt trauma

The most common cause of blunt trauma is the motor vehicle accident (MVA). Speed is a critical factor: a 10 per cent increase in impact speed translates to a 40 per cent rise in the case fatality. Ejection from a vehicle is associated with a significantly greater incidence of severe injury. The use of seatbelts reduces the risk of

death or serious injury for front-seat occupants by approximately 45 per cent (Figure 24.1). Although seatbelts reduce mortality overall, they can cause a specific pattern of internal injuries. Patients with seatbelt marks have been found to have a four-fold increase in thoracic trauma and an eight-fold increase in intra-abdominal trauma compared with those without seatbelt marks (Figure 24.2 and Summary box 24.2).

Summary box 24.2

Energy and injury prevention

- A 10 per cent increase in speed of impact increases pedestrian fatality risk by 40 per cent
- Seatbelts reduce the risk of injury in a vehicle by 45 per cent

In direct frontal MVAs, airbags provide a reduced risk of fatality of approximately 30 per cent. However, airbags themselves may also cause specific patterns of injury. In order to reduce the risk of airbag-induced injury, children younger than 12 years should be properly restrained in the back seat. Infants (aged <1 year) in rear-facing child safety seats should never ride in the front seat of a vehicle fitted with an activated passenger-side airbag.

Motorcyclists experience a significantly higher mortality rate than the occupants of cars, and fractures of the lower extremities are also more common in this group.

Penetrating trauma

Although the incidence of penetrating injuries is increasing, such injuries are less common in the UK compared with other countries. Important factors include the proximity of the underlying viscera to the path of the penetrating object, and the velocity of the missile. The distance from the weapon to the wound may give important information regarding the energy of the injury and therefore predict internal damage.

Figure 24.1 Unrestrained driver with severe craniofacial injury (courtesy of Johannesburg Hospital Trauma Unit).

Figure 24.2 Seatbelt mark after motor vehicle accident (courtesy of Johannesburg Hospital Trauma Unit).

Blast injury

Terrorism is now a global phenomenon. It is conceivable that civilian as well as military surgeons will be exposed to patients injured in explosions.

Crush injury

See Chapter 32 on disaster surgery.

Thermal injury

See Chapter 30 on burns.

Alcohol and drugs

Alcohol and other forms of substance abuse are major associated factors in all forms of trauma. Drivers with illegal blood alcohol levels account for nearly one-third of non-fatal injuries, and half of driver deaths. Injury to drunken pedestrians shows an even greater correlation with alcohol.

ASSESSMENT AND MANAGEMENT OF THE SERIOUSLY INJURED

Following major trauma, there is a well described 'trimodal distribution of death'.

The three 'peaks' as follows:

- 1 **Immediate**, 50 per cent of all deaths. These are probably not possible to save. They are usually the result of massive head injury or severe cardio-pulmonary insult.
- 2 **Early**, within the first few hours. These will result from a failure of oxygenation of tissue either because oxygen is not getting into the body (airway or breathing problem), or because the circulation has failed and so oxygen cannot be delivered to the tissues.
- 3 **Late**, 20 per cent of deaths. Usually from multiple organ failure and sepsis, influenced by inadequate early resuscitation and care.

The ATLS principles are aimed primarily at the 'early' group of patients. They try to optimise the speed and accuracy of the initial assessment and management, and so reduce subsequent morbidity and mortality.

The multidisciplinary team approach

A team approach is important for achieving the best possible outcome for traumatised patients. The 'trauma team' should be assembled and organised prior to patient arrival, with a nominated leader, and each team member should be assigned a specific role. Clear and concise communication among the team members is essential. Support staff such as radiographers, laboratory technicians and porters should also be immediately available.

PRIMARY SURVEY AND RESUSCITATION

The initial management of the traumatised patient must first consist of a rapid primary evaluation and resuscitation of vital functions as soon as abnormalities are detected. Only when the patient has been stabilised and the team are content with the primary survey is a more detailed secondary assessment carried out. The primary survey comprises the fundamental principles of the ATLS system, the 'ABCDE' of trauma care (Summary box 24.3).

Summary box 24.3

ABCDE of trauma care

- **A**, Airway with cervical spine protection
- **B**, Breathing and ventilation
- **C**, Circulation with haemorrhage control
- **D**, Disability: neurological status
- **E**, Exposure: completely undress the patient and assess for other injuries

Airway with cervical spine protection

In every trauma situation, the patient's airway is of paramount importance, and hence this is assessed first. If there is a vocal response from the patient, then the airway cannot be immediately compromised. Ensuring a patent airway may require simple measures, such as clearing the mouth and suction, or manoeuvres such as a jaw thrust or chin lift. If the airway is compromised again as soon as the chin lift or jaw thrust are relaxed, then a nasopharyngeal or Guedel airway should be used, provided that the patient will tolerate it.

In the case of severe head trauma, where the patient is unconscious (a Glasgow Coma Score (GCS) of 8 or less), then a definitive airway (such as endotracheal intubation) may be required.

It is important to suspect that every patient who has had significant trauma (especially to the head) has a cervical spine injury until proven otherwise. Therefore, throughout the initial assessment, the cervical spine must be immobilized providing that this is not impairing their safety or their airway. This is either performed manually, with in-line immobilization techniques, or with the traditional collar, sandbags and tape. Any efforts to maintain airway patency must also bear in mind the safety of the potentially unstable cervical spine (Summary box 24.4).

Summary box 24.4

Airway assessment

- Ensure cervical spine immobilization and check for vocal response
- Clear mouth and airway if obvious foreign bodies
- Jaw thrust and chin lift, if required
- Consider airway adjuncts
- If Glasgow Coma Score ≤ 8 , consider a definitive airway

Breathing and ventilation

Oxygen should be administered to all trauma patients, using a high concentration mask with a reservoir. Ventilation requires an adequately functioning chest wall, lungs and diaphragm, and each must be systematically evaluated. A check should be made for signs of surgical emphysema, dilatation of the neck veins, asymmetry of the chest wall, excessive respiratory effort and abnormal rate. Your findings should be recorded, as it is a change

The **Glasgow Coma Score** was introduced in 1977 by William Bryan Jennet, Professor of Neurosurgery and Graham Michael Teasdale, a neurosurgeon at the University Department of Neurosurgery at the Institute of Neurological Sciences, The Southern General Hospital, Glasgow, UK. Professor Teasdale was later knighted and became President of the Royal College of Physicians and Surgeons of Glasgow.

in these parameters which may be more useful in determining emergency treatment than any absolute finding. Percussion and auscultation should be performed on both the front and back of the chest wall after log rolling.

Tension pneumothorax, a flail chest with contusion, a massive haemothorax and an open pneumothorax are examples of life-threatening injuries that must be identified and treated in the primary survey. Critical findings include the tracheal deviation, absence of or asymmetry of breath sounds, hyper-resonance (consistent with tension pneumothorax) or dullness to percussion (haemothorax). However, these signs are often not as easy to pick up in the emergency room as they are to learn in a textbook. Therefore, the diagnosis must be assumed in any patient whose oxygenation is deteriorating despite a patent airway and a good ventilator effort. A tension pneumothorax should be immediately decompressed with the insertion of a needle into the second intercostal space, midclavicular line. This can then be followed by definitive chest drain insertion at an appropriate time. Open chest wounds should be occluded with a three-sided dressing, then an intercostal drain is inserted through a separate incision. If there is evidence of massive haemothorax (>1.5 L of blood), this may lead to severe respiratory compromise, cardiac tamponade and compression of the affected lung. Inserting a chest drain to drain the blood without any accompanying effort to control the haemorrhage may lead to a rapid and terminal deterioration in the patient's condition (Summary box 24.5).

Summary box 24.5

Breathing

- Give 100 per cent oxygen at high flow
- Inspect/percuss and auscultate chest
- Check for tension pneumothorax and immediately decompress if suspected
- Insert chest drain for haemothorax/pneumothorax
- Major vessel bleeding within the chest needs to be controlled

Circulation and control of bleeding

Assessment here centres on three critical clinical observations:

- 1 **Conscious level.** If this is impaired or altered, in the absence of obvious head injury, one must assume that the patient has lost a significant amount of blood and that cerebral perfusion has become compromised.
- 2 **Skin colour.** A patient with pink skin and warm peripheries is rarely critically hypovolaemic, and the converse is true for a pale, ashen, grey-looking patient with ominous signs of hypovolaemia.
- 3 **Pulse.** A full, slow, regular peripheral pulse is usually the sign of relative normovolaemia, whereas a rapid, thready pulse or, worse still, one that is not peripherally palpable is a grave sign of hypovolaemic shock, and blood volume must be rapidly restored.

While the primary survey is being carried out, other team members should be securing two large-bore cannulae for intravenous access. Fluid resuscitation should be titrated against the patient's response to the initial fluid challenge and their vital signs. Potential sites for major blood loss include the chest cavity, the abdomen, the pelvis and long bone fractures. Each of these must

be examined in turn. Surgical intervention may ultimately be required to control haemorrhage (Summary box 24.6).

Summary box 24.6

Circulation

- Check pulse and blood pressure
- Secure two large-bore cannulae, take bloods and commence fluid resuscitation
- Examine for evidence of blood loss and treat accordingly

Disability

The neurological status of the patient should be rapidly assessed. The pupils are monitored for size and reactivity, and a GCS measured. This should be repeated regularly as the test is quick to perform and once again it is change in the score which is more important in determining how treatment is going than one isolated measurement. Other than severe head injury, other reversible causes of an altered level of consciousness include hypovolaemia, hypoglycaemia, alcohol and drug abuse. These must all be excluded or treated during the initial assessment.

Exposure

The patient must be fully exposed and examined front and back using a carefully controlled log roll. Spinal alignment must be maintained during this procedure with in-line traction. Hypothermia can be rapid following trauma, and warming air blankets are vitally important in the resuscitative phase.

Adjuncts to the primary survey

At the same time as intravenous access is secured, blood should be taken for haematological and biochemical analysis. A 'group and save' and cross-match should also be requested. Additional monitoring should be attached to the patient, including a blood pressure cuff, 12-lead electrocardiography (ECG) monitoring and pulse oximetry. Arterial blood gas sampling gives a very quick idea of oxygenation, ventilation, and electrolyte imbalance. Additional adjuncts include a nasogastric tube, urinary catheter and a 'trauma series' of radiographs. Other, more specialised forms of imaging, such as ultrasound, computed tomography (CT) and angiography, should be considered once the patient's condition is seen to be stable after the initial assessment and resuscitation (Summary box 24.7).

Summary box 24.7

Adjuncts to the primary survey

- Blood tests – full blood count, urea and electrolytes, clotting screen, glucose, toxicology, cross-match
- ECG, pulse oximetry, arterial blood gas (ABG)
- Two wide-bore cannulae for intravenous fluids
- Urinary and gastric catheters
- Radiographs of the cervical spine, chest and pelvis

SECONDARY SURVEY

The secondary survey does not begin until after the primary survey has been completed, and all potentially life-threatening

injuries have been dealt with. In the case of a severely injured patient, for example, the secondary survey may not commence until the patient has returned from the operating theatre, having had life-saving surgery for primary survey 'ABCDE' problems.

The purpose of the secondary survey is to identify all other injuries and perform a more thorough 'head to toe' examination. If possible, it is here that the patient's history is reviewed. The 'AMPLE' mnemonic from the ATLS group is helpful here (Summary box 24.8).

Summary box 24.8

Review of patient's history (AMPLE)

- Allergy
- Medication, including tetanus status
- Past medical history
- Last meal
- Events of the incident

Secondary survey physical examination

Examine each region of the body for signs of injury, bony instability and tenderness to palpation.

- **Head and face.** Evaluate the head for penetrating injuries and depressed fractures, and any evidence of bleeding or discharge from the ears suggestive of a basal skull fracture (Chapter 25). Check the face for maxillofacial fractures and ocular injury. Inspect the mouth, mandible, zygoma, nose and ears. Exclude midfacial injury and potential airway compromise (Chapter 27).
- **Neck.** Inspect and palpate the cervical spine anteriorly and posteriorly for haematomas, crepitus, tenderness and evidence of steps on palpation. The spine is held immobilised until formally cleared clinically and radiographically (Chapter 26).
- **Chest.** Review the primary survey and perform full palpation and auscultation of the chest wall. Palpate the entire chest wall including the clavicle, sternum and ribs.
- **Neurological.** Examine the GCS regularly. Perform a full neurological examination if the patient's condition allows. Any evidence of sensory and motor disturbance requires full spinal immobilisation and urgent review by the neurosurgeons or spinal orthopaedic surgeons with imaging as appropriate.
- **Abdomen and pelvis.** Inspect for distension, bruising or penetrating wounds. Inspect and palpate for tenderness and signs of peritonism. Palpate the iliac crests for pain which might indicate pelvic instability, resulting from ring fractures. Inspect the perineum for evidence of ecchymosis or bleeding. A rectal examination is needed to assess tone, prostate level and to look for bleeding (Chapter 28).
- **Extremities.** It is often here that attention is diverted immediately when a dramatic injury to the limbs presents itself (Figure 24.3). It is important to note that, unless there is severe haemorrhage, the injury to the limb is not immediately life threatening and focus must be maintained on the primary survey and 'ABCDE' sequence. Obviously, deformed limbs should be manipulated into as near anatomical alignment as possible, remembering to document the distal neurovascular status before and after the intervention.

- **Log roll.** Once the patient has been evaluated anteriorly, a log roll should be performed to inspect the back. One member of the team is responsible for maintaining in-line spinal stabilisation (usually the anaesthetist when the patient is intubated.) Three other trained staff hold the patient steady through the turn. Inspect and palpate the entire spine from occiput to sacrum, looking and feeling for tenderness and bony abnormalities. Identify any penetrating injuries or exit wounds from gunshot injuries and cover these once they have been photographed. Percuss, palpate and auscultate the posterior chest wall.

Re-evaluation

This cannot be stressed enough. It is an integral process in the initial assessment of major trauma and should not stop once the patient leaves the emergency room. Continuous monitoring is invaluable here, especially of the vital signs and urinary output.

It is also very important to stress that, should the patient's condition change at any time during the initial assessment, then the primary survey must be repeated from the beginning, since additional life-threatening injuries may be declaring themselves.

Definitive care and transfer

Definitive care will be discussed in subsequent chapters, but it is important to recognise that there should be as little delay as possible in reaching this stage where initial resuscitation and assessment has been completed. It has increasingly been recognised that early transfer to an appropriate care facility is the most important contributor to successful outcome. When it becomes mandatory to transfer the patient from the initial receiving hospital, the patient must be haemodynamically and cardiovascularly stable. An experienced anaesthetist should accompany the patient, the airway should be secured as necessary. Life-saving surgery may need to be performed prior to transfer for other injuries. This is called 'damage control surgery' (Chapter 32).

SPECIAL SUBGROUP CONSIDERATIONS

The initial management of any traumatised individual initially follows the same methodical 'ABCDE' pathway. However, there are three very important subgroups which require special consideration: the paediatric, the elderly and the pregnant. Each will be considered separately, highlighting the differences in initial assessment and management.

Paediatric trauma

Injury is the leading cause of mortality among children and adolescents. Children have a smaller body mass and, therefore, there may be a greater force applied per unit surface area for a given injury. The energy is transmitted to a body with less fat, less connective tissue and an immature skeleton; therefore, injuries to more than one organ are more frequent. As the surface area to body volume ratio of children is high, thermal energy loss is higher and hypothermia is a higher risk.

Airway and cervical spine control

As with any traumatised patient, control of the airway is the first priority. Anatomically, children differ from adults in that they have a smaller and more anteriorly positioned and funnel-shaped larynx, floppy epiglottis, short trachea and large tongue. Nasotracheal intubation in children younger than nine years

Figure 24.3 (a–d) Severe degloving injuries to the upper and lower limbs following a high-speed road traffic accident. The initial appearance and severity of the injury should not detract from following the important Advanced Trauma Life Support (ATLS) sequence in evaluating and treating immediate life-threatening injuries.

should not be performed because of the possibility of damage to the cranial vault and to the fragile soft tissues causing bleeding. With respect to a definitive airway, cuffed tubes are rarely indicated for children less than nine years of age because of the delicate structures within the airway and the fact that the cricoid ring provides an adequate seal. It should also be remembered that in children, the trachea is relatively short, and care should be taken not to intubate the right main bronchus.

Breathing and ventilatory control

The respiratory rate in the child decreases with age. Infants require 40–60 breaths per minute, whereas the older child has a rate of 20 breaths per minute (Table 24.2). Hypoxia is a

common cause of cardiorespiratory arrest; however, before this, hypoventilation causes a respiratory acidosis, which is the most common acid–base disturbance in the injured child. Correction must be through adequate and controlled ventilation. Flail chest and aortic rupture are uncommon in children due to the elastic nature and resilience of the underlying structures. Pulmonary contusions are not evident in the early chest x-ray, but as before, re-evaluation is necessary for the following 24–48 hours.

Circulation with haemorrhage control

Vital signs vary with age (Table 24.2). Due to the greater physiological capacity and ability of children to compensate for fluid loss, hypotension is a very late and ominous sign of hypovolaemia.

Table 24.2 Paediatric vital signs.

Normal vital signs by age	Pulse (beats per min)	Systolic blood pressure (mmHg)	Respiratory rate (breaths per min)
Infant (<1 year)	160	80	40
Preschool (<5 years)	140	90	30
Adolescent (>10 years)	120	100	20

mic shock. Once they have become hypotensive, deterioration can be rapid and fatal. If intravenous access has failed after two attempts, consideration should be given to intraosseous access, especially in children younger than six years of age. The uninjured proximal tibia is the ideal route or, alternatively, the distal femur.

Disability

Head injury is the most common cause of disability and death among children in trauma. The principles of assessment and management are similar to those in the adult population with strict avoidance of hypoxia and hypovolaemia. Diffuse axonal injury is more common in children than in adults, who have a higher incidence of intracranial mass lesions.

Exposure

As mentioned above, surface area to volume ratios make children particularly vulnerable to environmental changes, especially hypothermia. Overhead lamps or heaters, warming blankets and warmed intravenous fluids and blood are often necessary (Figure 24.4).

Paediatric secondary survey

This is essentially similar to the head to toe examination described for adults. Consideration must be given to the fact that the liver and spleen are the most common organs to be injured in the abdomen. A number of specific visceral injuries are more common in children:

- duodenal haematoma or pancreatic injury: secondary to a bicycle handlebar striking the right upper quadrant relatively unprotected by an underdeveloped anterior abdominal musculature;
- small bowel perforation and mesenteric injuries;
- bladder injury: more common due to pelvic shallowness (Table 24.3);

- restraint from a lap belt (less common now) results in enteric disruption, especially if there is an associated 'chance' fracture of the lumbar spine.

Child abuse

Whenever managing paediatric trauma, non-accidental injury (NAI) must always be considered. It is our responsibility as health-care professionals to safeguard these children and prevent them from further harm. There are certain features from both the history and examination that may point towards NAI, and early identification and alerting of child protection authorities is essential (see Table 24.4).

Trauma in the elderly population

Trauma in the elderly population presents many challenges for the treating physicians due to the fragility of the patient's physiological status and comorbidities. It does not require high-velocity or high-energy trauma to put the elderly life at risk following injury. An elderly patient may only be surviving with just enough physiological reserve, and any injury, no matter how insignificant, may prove fatal (Figure 24.5). Initial assessment and, more importantly, management has to be even more meticulous in this subgroup of patients.

Airway and cervical spine control

This is the same for the elderly as it is in the normal population. However, one should watch for dentition status, nasopharyngeal

Table 24.3 Urine output by age in the paediatric population.

Age	Optimal urine output
Infant (<1 year)	2 mL/kg per hour
Preschool (1–5 years)	1.5 mL/kg per hour
Child–adolescent (6–16 years)	1 mL/kg per hour

Figure 24.4 External warming blanket (courtesy of Johannesburg Hospital Trauma Unit).

Table 24.4 Markers for non-accidental injury

Repeated hospital visits for minor injuries
Late presentations and multiple visits to different hospitals
Vague or inconsistent history from the child's parent or guardian and the child
Withdrawn behaviour of the child with resistance to examination
History of abuse in a sibling
Bite marks, finger marks, belt marks or cigarette burns
Multiple fractures of different ages
Perineal injury
Intracranial haemorrhage without a history of motor vehicle accident

fragility as in children, macroglossia and cervical spine and temporomandibular joint arthritis. Stiffness in the cervical spine may make the usual airway clearing measures difficult.

Figure 24.5 Classical shortened externally rotated right lower limb of a subcapital fractured neck of femur – it should be emphasised that this represents a significant major trauma in this vulnerable group of elderly individuals.

Breathing and ventilation

In patients with a known history of chronic obstructive airways disease, it may be prudent to consider early intubation and ventilation because of their instability in maintaining respiratory drive. However, it should also be remembered that they may prove very difficult to extubate too. Mortality rates following chest injuries in the elderly are higher; rib fractures and pulmonary contusion are not well tolerated. Pulmonary complications, such as atelectasis, pneumonia and pulmonary oedema, occur with great frequency.

Circulation

By the age of 65 years, nearly half of the population has some coronary artery stenosis. Cardiac reserve and maximum potential heart rate decreases with age and, therefore, it may be difficult to detect ongoing hypovolaemic shock. Furthermore, many of the elderly population may be taking cardiac medication that may mask a compensatory tachycardia following trauma, e.g. beta-blockers. Urinary response also changes with age; the elderly kidney is also more susceptible to damage from hypovolaemia, medications and other nephrotoxins. Retroperitoneal haemorrhage may occur from relatively minor pelvic or hip fractures, and a patient who fails to stabilise after fluid resuscitation may require prompt angiography and embolisation. Prompt treatment or transfer to an appropriate facility may be life-saving.

Disability

Cerebral atrophy is common with increasing age. This leads to increased space within the cranium and therefore some protection from contusion. Pre-existing medical conditions may be a cause of confusion in the elderly, making assessment of head injury difficult. This is where a change in conscious state between two observations is more useful than a single measurement. Osteoporosis can lead to increased risk of spinal fractures after even very minor injury. Spinal injury may also be more common because of pre-existing stiffness and spinal stenosis. This rigidity predisposes the patient to central and anterior cord syndromes.

Exposure

Reduced thermoregulatory ability is well documented in the elderly. It is important that, as in children, the elderly patient is protected from the effects of hypothermia during the initial assessment and management.

Secondary survey in the elderly

A full head to toe examination needs to be undertaken after careful 'AMPLE' history-taking (where possible). Owing to the friable skin condition, spinal injury should be ruled out quickly, and prolonged use of the spinal board should be avoided, reducing the risk of pressure sores. Skin vascularity and dermal thickness fall with age, so skin is more likely to break down and then, when it does, it heals badly. It is commonly a musculoskeletal injury that the patient presents with after a fall, usually a consequence of pre-existing osteoporosis or osteopenia. The most common fracture is in the proximal femur followed by the humerus and wrist. Above all, a multi-disciplinary approach must be adopted including the patient and their relatives if the definitive treatment plans are to be successful.

Trauma in pregnancy

For the purposes of trauma management, pregnancy must be considered and excluded in all women of child-bearing age. Anatomic and physiological changes must be considered when assessing and resuscitating a pregnant woman. The trauma team in this situation should include both an obstetrician for early assessment of the fetus, and potentially a paediatrician. The fundamental principles of the ATLS system remain the same and although there are two patients, the best chance of a favourable outcome for the foetus, is with optimal resuscitation of the mother.

During the primary survey, the uterus of the third trimester pregnant patient should be manually displaced to the left side in order to take pressure off the inferior vena cava. This promotes venous return to the heart and increasing cardiac output in a potentially shocked state. Due to the increased intravascular volume in pregnancy, these patients can lose significant amounts of blood before they display the usual signs of hypovolaemia. This is important to understand and recognize since the mother may appear relatively stable while the fetus is in distress due to a lack of placental perfusion.

The potential for fetomaternal haemorrhage must always be considered in the traumatized pregnant patient, since only a minor haemorrhage could result in the sensitization of a Rhesus negative mother. Therefore, all Rh-negative patients should be administered Rh immunoglobulin when there is a concern about potential fetomaternal haemorrhage.

SUMMARY

Trauma is a massive and growing worldwide health burden. Despite injury prevention strategies, a significant number of the

world's population will be exposed to or involved in trauma. In the initial assessment and management of these patients, it is demonstrated that the ATLS approach is still the most reproducible protocol for a successful outcome. A team approach must be utilised, and good organisation of the system leads to very real reductions in mortality and morbidity globally. The paediatric and elderly are special groups of individuals who have unique inherent differences that must be recognised but, essentially, the framework for assessment remains the same. It is only through education and training that truly significant inroads can be made into this hugely debilitating and resource-intensive 'disease'.

LEARNING OBJECTIVES

To understand:

- The physiology of cerebral blood flow and the pathophysiology of raised intracranial pressure
- The management of head injury and prevention of secondary brain injury
- The diagnosis and management of spontaneous intracranial bleeding including subarachnoid haemorrhage

PHYSIOLOGY AND PATHOPHYSIOLOGY

Cerebral blood flow

The brain is dependent on continuous cerebral bloodflow for oxygen and glucose delivery, and hence survival. Normal cerebral blood flow (CBF) is about 55 mL/minute for every 100 g of brain tissue. Ischaemia results when this rate drops below 20 mL/min, and even lower levels will result in infarction unless promptly corrected.

The flow rate is related to cerebral perfusion pressure (CPP), the difference between mean arterial pressure (MAP) and intracranial pressure (ICP): $CPP (75-105 \text{ mmHg}) = MAP (90-110 \text{ mmHg}) - ICP (5-15 \text{ mmHg})$.

Typical normal values are given in parentheses. In fact, in the normal brain, variations in vascular tone maintain a constant CBF across a range of MAP between 50 and 150 mmHg, and a corresponding range of CPP, a process termed 'cerebral autoregulation'. The limits of this range are elevated in patients with chronic hypertension.

Neurosurgical emergencies, especially head injury, lead to brain swelling, bleeding and hydrocephalus. The common pathophysiological pathway is then elevated ICP and reduced CPP and CBF.

Other factors which may compromise CBF include the failure of autoregulation which follows brain insult, and vasospasm after aneurysm rupture (see below under Aneurysmal subarachnoid haemorrhage).

ICP and the Monro Kellie doctrine

Alexander Monro observed in 1783 that the cranium is a 'rigid box' containing a 'nearly incompressible brain'. Therefore any expansion in the contents, especially haematoma and brain swelling, may be initially accommodated by exclusion of fluid components, venous blood and cerebrospinal fluid (CSF). Further expansion is associated with an exponential rise in intra-

cranial pressure (see Figure 25.1). The result is hypoperfusion and herniation.

Herniation syndromes

The rapid increase in intracranial pressure which accompanies the exhaustion of compensation mechanisms ultimately results in herniation of brain tissue. The uncus of the temporal lobe may herniate over the tentorium resulting in pupil abnormalities (see below under Pupils), usually occurring first on the side of any expanding haematoma. Cerebellar tonsillar herniation through the foramen magnum compresses medullary vasomotor and respiratory centres, classically producing Cushing's triad of hypertension, bradycardia and irregular respiration (Summary box 25.1).

Summary box 25.1

Intracranial pressure

- Perfusion of the brain with oxygenated blood is critical for its survival
- Cerebral perfusion pressure is the difference between mean arterial pressure and intracranial pressure
- Cerebral perfusion is kept constant across a range of perfusion pressures by the process of autoregulation
- Autoregulation is compromised in the injured brain

HEAD INJURY

Epidemiology

Head injury accounts for 3–4 per cent of emergency department attendances, with around 1500 cases per 100 000 population per year in the UK. Of these, 300 per 100 000 require admission, 15 to a neurosurgical unit. Annual mortality attributable to head injury is estimated at nine per 100 000, and it remains

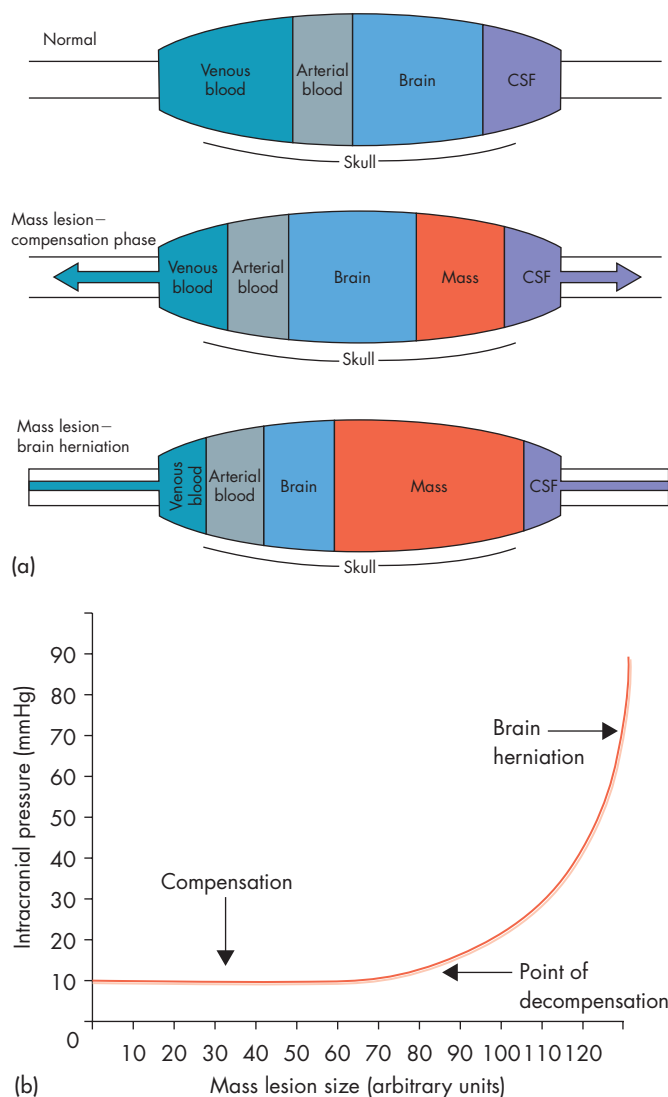

Figure 25.1 (a, b) Initially, compensation for this expansion within the cranium is compensated for by displacement of CSF and venous blood. When this mechanism has no further reserve capacity, the intracranial pressure increases rapidly. The result is hypoperfusion and herniation.

the leading cause of death and disability from childhood to early middle age.

Risk factors include male sex, recreational drugs (including alcohol and substance abuse) and youth, with a peak at 15–30 years of age. This latter factor contributes to the overwhelming social and economic impact of head injuries, with an estimated 2 per cent of the US population suffering long-term disability as a result of head injury.

Road traffic accidents are the leading cause of head injury, being responsible for up to 50 per cent of cases. Other common mechanisms of injury include falls and assault. There is significant geographical variation, for example firearms are the third leading cause in the US.

Initial evaluation and management

Resuscitation is performed according to Advanced Trauma Life

Support (ATLS) guidelines, beginning with management of the airway and cervical spine control (see Chapter 24).

History

Vital information may need to be obtained from paramedics and observers when the patient is unable to give a full history (as is usually the case).

Mechanism

Head injuries arising from high energy mechanisms of injury, such as a fall from a height or a high-speed road accident. This makes multisystem injury (especially to the spine) likely so a full search should be made for these (see Chapter 24). In the case of road traffic accidents in particular, extraction time and evidence of hypoxia or haemodynamic instability at the scene is important information to obtain from the paramedics. The possibility that a fall or crash may have resulted from a prior medical problem, such as myocardial infarction, hypoglycaemia or subarachnoid haemorrhage, should be borne in mind when trying to get a full history (Summary box 25.2).

Summary box 25.2

The history in head injury

- Bystanders and paramedics may give vital information on the:
 - pre-injury state (fits, alcohol, chest pain)
 - energy involved in the injury (speed of vehicles, height fallen)
 - conscious state and haemodynamic stability of the patient after the accident
 - length of time taken for extrication
- The length of retro- and anterograde amnesia are useful for grading severity
- Check the medication history, especially anticoagulants

Neurological progression

A specific check should be made for any loss of consciousness at the time of injury, and its duration. The Glasgow Coma Score (GCS) and pupil responses at the scene and on arrival in Accident and Emergency should be obtained and documented. They should also be checked regularly thereafter. It cannot be overemphasised that deterioration in GCS is an important index of developing, and potentially reversible, secondary injury. It is also useful to assess the extent of amnesia, retrograde (events prior to the injury) and anterograde (events afterwards). If the patient was intubated at the scene of the accident, it is valuable to know whether the patient was moving all four limbs before this?

Other history

Obtain details of the patient's medical background, including allergies and normal medications. Of particular note here are antiplatelet agents, potentially requiring platelet transfusion especially if surgery is needed, and anticoagulants, which may need reversal.

Examination: primary survey

The primary survey is performed as normal (see Chapter 29). The priority in any resuscitation is to ensure uninterrupted per-

fusion of the brain with oxygenated blood. This is especially true after a head injury given the disturbance to intracranial autoregulation and the sensitivity of the primary injured brain tissue to further insult. Bleeding from scalp lacerations may require management as part of the primary survey, as the blood loss can be substantial and on-going.

Check the responsiveness of the pupils, conscious level and for any gross focal neurological deficits. Blood glucose level should also be measured as early as possible as hypoglycaemia is very dangerous and eminently reversible (Summary box 25.3).

Summary box 25.3

The primary survey in head injury

- Ensure adequate oxygenation and circulation
- Check pupil size and response and Glasgow Coma Score as soon as possible
- Check for focal neurological deficits before intubation if possible
- Check blood sugar for hypoglycaemia

Pupils

The pupil size should be recorded in millimetres, and reactivity documented as present, sluggish or absent. Uncal herniation (Figure 25.2) can compress the third nerve, compromising the parasympathetic supply to the pupil, so that unopposed sympathetic activity produces an enlarged and sluggish pupil, which then, if the compression continues, becomes fixed and dilated. However, an abnormal pupil size and response may reflect pathology anywhere in the eye or the reflex loop made up by the

Figure 25.2 Brain herniation. Herniation of the cingulate gyrus under the falx cerebri is called ‘subfalcine herniation’ (1). Herniation is associated with midline shift (2). Herniation of the uncus of the temporal lobe (3) is associated with compression of the ipsilateral third nerve. Central herniation (4) and tonsillar herniation (5) are associated with compression of brainstem structures.

optic nerve, the oculomotor nerve, and the brainstem. Direct ocular trauma or nerve injury in association with a skull base fracture can cause mydriasis (dilated pupil) present from the time of injury. Pre-existing discrepancy in pupil size (anisocoria), as a result of Holmes-Adie pupil or cataracts for example, may also complicate assessment.

Glasgow Coma Score

The GCS is the sum of scores on three components as detailed in Table 25.1. The breakdown of the GCS into eye opening, verbal and motor components should always be recorded and used when communicating the situation to other doctors. Remember that the score represents the best performance elicited, so a patient flexing in response to a painful stimulus on the left and localising on the right scores ‘M5’. A sternal or supraorbital rub, or trapezius squeeze will usually be an appropriate stimulus. Remember that 3/15 is the lowest possible GCS score!

Table 25.1 Head injury severity: clinical classification.

Eyes open	Spontaneously	4
	To verbal command	3
	To painful stimulus	2
	Do not open	1
Verbal	Normal oriented conversation	5
	Confused	4
	Inappropriate/words only	3
	Sounds only	2
	No sounds	1
	Intubated patient	T
Motor	Obeys commands	6
	Localises to pain	5
	Withdrawal/flexion	4
	Abnormal flexion	3
	Extension	2
	No motor response	1

Neurological deficit

Gross focal neurological deficits, such as paraplegia, may be evident at the primary survey, and an assessment to exclude such deficit should be carried out, especially if the patient is to be intubated so that subsequent examination will be impossible. Detailed neurological examination is included in the secondary survey.

Examination: secondary survey

A full secondary survey will be required. Particular attention must be paid to the head, neck and spine.

Head

Examination of the head should include inspection and palpation of the scalp for evidence of subgaleal haematoma and scalp lacerations, which may bleed profusely, and potentially overlie fractures. Examine the face for evidence of fractures, especially to the orbital rim, zygoma and maxilla. Clinical evidence of a skull base fracture may include Battle’s sign (bruising over the mastoid, see Figure 25.3), and ‘racoon’ or ‘panda’ eyes (bilateral periorbital bruising). Haemotympanum, or overt bleeding from

Sir Gordon Morgan Holmes, 1876–1965, physician, The National Hospital for Nervous Diseases, Queen’s Square, London, UK.
William John Adie, 1886–1935, physician, The National Hospital for Nervous Diseases, Queen’s Square, London, UK.

Figure 25.3 Battle's sign. A skull base fracture may be associated with bruising over the mastoid process.

the ear if the tympanic membrane has ruptured, and CSF rhinorrhoea or otorrhoea (clear cerebro spinal fluid usually mixed with blood coming from the nose or the ear) are also highly suggestive of a fracture of the base of the skull.

A complete examination of the cranial nerves will reveal, for example, facial or vestibulo-cochlear nerve damage associated with skull base fracture. Midbrain or brainstem dysfunction may produce gaze paresis (inability of eye to look across beyond the midline), dysconjugate gaze (inability of the eyes to work together), or roving eye movements. Inspect the conjunctiva

Figure 25.4 A right frontal comminuted depressed skull fracture, with a linear undisplaced fracture of the right parietal bone visible posteriorly.

and cornea of the eyes, and the retina using an ophthalmoscope, looking for hyphaema (blood in the anterior chamber of the eye), papilloedema or retinal detachment. Blood in the mouth may be due to tongue-biting at seizure or at the time of trauma.

The GCS and pupil status, assessed as part of the primary survey, require re-evaluation at the secondary survey and regularly thereafter (Summary box 25.4).

Summary box 25.4

Examination of the head (secondary survey)

- Look and feel over the whole skull and face for cuts, bruises and fractures
- Check for fractured base of skull by looking for blood in the ears, nose or mouth and Battle's sign
- Check the cranial nerves
- Check the eyes for movement and for damage to the orbit itself

Neck and spine

In moderate or severe traumatic brain injury (TBI), there is an associated cervical spine fracture in around 10 per cent of cases. Therefore, cervical spine injury must be presumed in the context of head injury until actively excluded. In a high energy mechanism, such as road traffic accident or fall from a height, thoracic and lumbar spine injuries must also be excluded. Plain x-rays are of limited value in excluding significant cervical spine injury. Even computed tomography (CT) imaging does not exclude the possibility of significant ligamentous injury. Therefore, where possible, these patients should be managed in a hard collar until their spine can be cleared clinically.

A peripheral nerve examination with documentation of limb tone, power, reflexes and sensation needs to be performed early to identify spinal pathology. This is especially important in patients who may subsequently be intubated and ventilated when this assessment will no longer be possible. Obtunded (partially conscious) patients should move all four limbs in response to an appropriate painful stimulus.

The patient will need to be log-rolled to palpate for thoracic or lumbar deformity, and any cervical collar should be removed at this stage to allow palpation of the cervical spine, before it is then replaced again. If there is associated spinal injury, a thoracic sensory level is much more easily established by sensory examination on the back. A per rectal examination is also performed at log-roll, assessing for anal tone, sensation in the awake patient, and anal wink (sphincter seen to contract in response to a pinprick stimulus). Priapism is a strong predictor of severe cord injury even in intubated patients (Summary box 25.5).

CLASSIFICATION OF SEVERITY AND TYPE OF HEAD INJURY

Glasgow Coma Score

Severity of head injury is classified according to the Glasgow Coma Score (Table 25.1), as it is the GCS – and in particular the motor score – that is the best predictor of neurological outcome. On-going impaired conscious level, beyond isolated

Summary box 25.5**Examination of the whole patient in head injury**

- Cervical spine injury is common in patients with head injuries
- Even obtunded patients should move all four limbs
- Check and record power, tone and sensation in the peripheral nerves
- Log roll to check the whole spine for steps and tenderness
- Perform a rectal examination to check for anal tone and anal wink
- Check for priapism

confusion and amnesia, implies a moderate injury and coma suggests a severe injury.

Important aspects of injury

Head injuries can be divided into three categories which overlap and in which more than one may be present in a patient. These are diffuse (the brain has been shaken), blunt (a direct non-penetrating blow) and penetrating (the cranium has been breached). Rapid deceleration often produces shearing of axons (diffuse axonal injury) and coup–contrecoup contusions (see below under Cerebral contusions). Penetrating injuries can be classified as low velocity or high velocity. The cavitation caused by high velocity injuries is especially damaging to the brain. Skull fractures can be open or closed. If intracranial air can be seen on the x-ray, then the dura has been breached too. Fractures may be linear (when they can be difficult to see on x-ray) or comminuted when they may also be depressed. Fractured base of skull may present with bleeding from the eyes, ears nose or mouth or with rhinorrhoea (CSF leaking from the nose).

Intracranial haematoma

Haemorrhage within the cranium occurs in four main sites: extradural, subdural, subarachnoid and intraparenchymal. Each has a characteristic cause, presentation and treatment, which will be discussed below. However, a common characteristic is that all cause a rise in intracranial pressure, which may compromise perfusion of the brain. Minimising the secondary injury by making sure that the patient is well oxygenated and that their blood pressure is within normal limits is important in the early management of these cases (Summary box 25.6).

Summary box 25.6**Classification of traumatic head injuries**

- Scalp: open and closed (beware air under the dura)
- Skull site: vault and base of skull
- Skull type: linear, comminuted and depressed
- Intracranial bleeding: extradural, subdural, subarachnoid and intraparenchymal
- Brain tissue causes: diffuse, blunt (direct, coup–contrecoup) and penetrating

MANAGEMENT OF MINOR AND MILD HEAD INJURY

In general, patients without on-going deficits can safely be discharged from the emergency department, provided they meet the criteria listed (Table 25.2). An observation period of a few hours is advisable, especially where there is history of loss of consciousness at the time of injury: this avoids discharge during the ‘lucid interval’ which may precede delayed deterioration due to an expanding intracranial haematoma.

Patients who do not meet all the discharge criteria will need admission for a further period of observation, and in this case it may be more economical to perform a CT to allow safe early discharge in this group. In the UK, the National Institute for Health and Clinical Excellence (NICE) also recommends CT imaging in patients with a persistent reduced conscious level, focal deficits, suspected fractures or risk factors for intracranial bleed (see Table 25.3).

Table 25.2 Discharge criteria in minor and mild head injury.

- GCS 15/15 with no focal deficits
- Normal CT brain if indicated (see below)
- Patient not under the influence of alcohol or drugs
- Patient accompanied by a responsible adult
- Verbal and written head injury advice: seek medical attention if:
 - Persistent/worsening headache despite analgesia
 - Persistent vomiting
 - Drowsiness
 - Visual disturbance
 - Limb weakness or numbness

CT, computed tomography; GCS, Glasgow Coma Scale.

Table 25.3 National Institute for Health and Clinical Excellence (NICE) guidelines for computed tomography (CT) in head injury.

- GCS <13 at any point
- GCS 13 or 14 at 2 hours
- Focal neurological deficit
- Suspected open, depressed or basal skull fracture
- More than one episode of vomiting
- Any patient with a mild head injury over the age of 65 years or with a coagulopathy, for instance warfarin use, should be scanned urgently
- Dangerous mechanism of injury or antegrade amnesia >30 minutes warrants CT within 8 hours

SURGICAL ASPECTS OF HEAD INJURY**Skull fractures**

Closed linear fractures are managed conservatively, with primary closure of associated wounds where possible. Skull base fractures may be complicated by CSF leak, pituitary dysfunction, arterial dissection or cranial nerve deficits, with anosmia, facial palsy or hearing loss typical. Prophylactic antibiotics are not usually required, even in the case of CSF leak, which generally resolves spontaneously without the need for craniotomy and

repair. Blind nasogastric tube placement is contraindicated in these patients.

Fractures which involve the air sinuses may be managed as open fractures, using broad spectrum antibiotics with or without exploration.

Depressed skull fractures involve inward displacement of a bone fragment by at least the thickness of the skull (Figures 25.4 and 25.5). They occur when small objects hit the skull at high velocity. They are usually compound (open) fractures, and are associated with a high incidence of infection, neurological deficit and late-onset epilepsy.

Most compound fractures will require exploration, debridement and elevation of the fragment. Prophylactic treatment with a course of broad spectrum antibiotics is normal practice (Summary box 25.7).

Summary box 25.7

Management of head injuries

- Early discharge if NICE criteria are met
- Scalp wounds need closure
- Significant depressed fractures need elevating, antibiotics and antiepileptics
- Skull base fractures may be associated with CSF leak. Pneumococcus vaccination is valuable, but prophylactic antibiotics are not usually indicated

Extradural haematoma

Extradural haematoma (Figure 25.6) is a neurosurgical emergency. It results from rupture of an artery, vein or venous sinus, in association with a skull fracture. Typically, it is damage to the middle meningeal artery under the thin temporal bone. A low energy injury mechanism, perhaps with brief loss of consciousness, is sufficient to start the extradural bleeding. The patient may then present in the subsequent lucid interval with headache, but without any neurological deficit. At this stage, the increase in the intracranial volume is not yet causing a significant rise in intracranial pressure because compensation is occurring. However, once the limits of compensation have been reached after as long as some hours (see Monro Kellie doctrine) rapid deterioration follows. There is contralateral hemiparesis, reduced conscious level and ipsilateral pupillary dilatation, the cardinal signs of brain compression and herniation. Although this classical presentation occurs in only one third of cases, it emphasises the potential for rapid avoidable secondary brain injury in patients with minimal primary injury.

On CT, extradural haematomas appear as a lentiform (lens-shaped or biconvex) hyperdense lesion between skull and brain, constrained by the adherence of the dura to the skull. Mass effect may be evident, with compression of surrounding brain and mid-line shift. Areas of mixed density suggest active bleeding. A skull fracture will usually be evident (Summary box 25.8).

Extradural haematoma requires immediate transfer to the most accessible neurosurgical facility, for immediate evacuation in deteriorating or comatose patients or those with large bleeds, and for close observation with serial imaging in all cases.

Overall mortality is around 10–20 per cent, but is considerably lower in isolated extradural haematoma.

Figure 25.5 (a–c) A small depressed skull fracture of the parietal bone visible on axial bone windows (a), visualized on bone vault reconstructions (b) and with an underlying breach of dura (c).

Summary box 25.8

Extradural haemorrhage

- Can occur in the context of apparently minor trauma
- Isolated extradural haematoma may manifest as sudden deterioration following a lucid interval
- Lentiform lesion on computed tomography
- Require immediate transfer to a neurosurgical unit for decision on evacuation

Figure 25.6 (a) A large left extradural haematoma (note the biconvex shape) exerts a mass effect; a smaller right acute subdural haematoma is also evident. (b) Right frontal intracerebral haematoma extending into the lateral ventricle is evident. There is a small right posterior extradural haematoma, and traumatic subarachnoid bleeding in the sulci of the right hemisphere. (c) A surgical temporal bone exposure showing a linear skull fracture with underlying extradural haematoma visible through a burr hole.

Acute subdural haematoma

Acute subdural bleeding arises from rupture of cortical vessels. In contrast to extradural haematoma (and chronic subdural haematoma), acute subdural haematoma is usually associated with a high energy injury mechanism and significant primary brain injury. Conscious level is usually therefore impaired at presentation, but may deteriorate further as the haematoma expands. Since the dura is not adherent to the brain as it is to the skull, subdural blood is free to expand across the brain surface giving a diffuse concave appearance (Figures 25.6a and 25.7a).

Acute subdural bleeds of significant size or with significant associated midline shift require evacuation, and the cumulative mortality in this group is about 50 per cent. Smaller bleeds in neurologically stable patients may be managed conservatively, with ICP monitoring, in a neurosurgical unit (Summary box 25.9).

Chronic subdural haematoma

The epidemiology and presentation are completely different from acute subdural haematoma. The patient is generally elderly, may be taking antiplatelet or anticoagulant medications, and there is usually a history of a recent fall, or falls. Cerebral atrophy commonly found in the elderly is believed to stretch bridging

Summary box 25.9

Subdural haemorrhage

- Relatively severe trauma
- No lucid interval
- Diffuse concave lesion on computed tomography
- Require immediate transfer to a neurosurgical unit for decision on evacuation
- 50 per cent mortality

veins. These can then rupture after only minor trauma, bleed, and then tamponade (stop bleeding due to the pressure which has been produced by the bleed). Subsequent degradation of the blood clot over days or weeks leads to osmotic expansion. It is this which produces the mass effect. Presenting features, just as for any expanding intracranial mass, include pressure symptoms, especially headache and drowsiness, neurological deficit and seizures. In this group, it is important to exclude coexisting electrolyte disturbance and infections, which may be contributory. Imaging reveals diffuse hypodensity overlying the brain surface. Recent bleeding may be isodense or hyperdense, and mixed density can indicate an acute-on-chronic subdural haematoma (Figure 25.7b).

Figure 25.7 (a) Right-sided acute subdural haematoma (hyperdense). The substantial midline shift reflects brain swelling as well as bleeding; this is a high energy injury. (b) Bilateral subdural haematomas: the left is mixed density, the hypodense material representing old blood and the higher density indicating more recent bleeding, probably loculated so requiring a craniotomy to evacuate. The bleed on the right is isodense, indicating intermediate age.

Drainage is performed using burr holes, often under local anaesthetic (especially in elderly patients who present a substantial anaesthetic risk). Urgency is dictated by the clinical condition of the patient. If clinically stable, a delay of 7–10 days to allow platelet function to normalise after withdrawal of aspirin may be considered. Anticoagulation should be reversed either by administration of vitamin K, or urgently by transfusion of recombinant clotting factors in patients who have deteriorated acutely. Occasionally, acute-on-chronic bleeds with residual solid clot or septations require a craniotomy for adequate clot evacuation (Summary box 25.10).

Summary box 25.10

Chronic subdural haemorrhage

- Occurs in the elderly, especially those on anticoagulants
- May take days or weeks to develop
- Diffuse hypodense lesion on computed tomography
- Evacuation may be delayed until clotting has been improved

Traumatic subarachnoid haemorrhage

Trauma is the most common cause of subarachnoid haemorrhage (Figures 25.6b and 25.8), and this is managed conservatively. It is not usually associated with significant vasospasm, which characterises aneurysmal subarachnoid haemorrhage (see below under Aneurysmal subarachnoid haemorrhage). The possibility of spontaneous subarachnoid haemorrhage actually leading to collapse and so causing a head injury needs to be borne in mind and formal or CT angiography may be required to exclude this.

Cerebral contusions

Contusions are common and are found predominantly where the brain is in contact with the irregularly ridged inside of the skull, i.e. at the inferior frontal lobes and temporal poles. ‘Coup–contrecoup’ injury describes contusion of the brain on the skull at the site of impact combined with contusion elsewhere sustained as the brain rebounds from the initial impact. Contusions appear heterogenous on CT, reflecting their composition of injured brain matter interspersed with acute blood (Figure 25.8). Contusions rarely require surgical intervention, but may warrant delayed evacuation to reduce mass effect.

Diffuse axonal injury

This is a form of primary brain injury, seen in the high energy accidents, and which usually renders the patient comatose. It is strictly a pathological diagnosis made at post-mortem, but

Figure 25.8 A large right extradural haematoma is evident. There are widespread cerebral contusions most prominent in the left frontal lobe. There is traumatic subarachnoid blood in the third and lateral ventricles.

haemorrhagic foci in the corpus callosum and dorsolateral rostral brainstem on CT may be suggestive, although the CT often appears normal.

Arterial dissection

Cerebral arterial dissection occurs spontaneously or in the context of trauma, which may be as trivial as nose-blowing or coughing. In the hours after significant trauma, dissection of the carotid extracranially, or at the skull base in association with fractures, is most common. It presents with headache, neck pain and focal ischaemic deficits, due to occlusion by mural haematoma, thrombus and thromboembolism. Intracranial dissection often affects the vertebral artery and may result in subarachnoid bleeding.

Development of a delayed deficit, especially in the context of a skull base fracture involving the carotid canal, should prompt urgent investigation and treatment. Carotid dissection is generally managed with anticoagulation, but vertebral dissection with subarachnoid haemorrhage usually requires surgical or endovascular intervention.

Non-accidental injury

Head injury in children and vulnerable adults may be due to abuse. Significant findings include delayed presentation, injuries of disparate age, retinal haemorrhages, bilateral chronic subdural haematomas, multiple skull fractures and neurological injury without external signs of trauma (Summary box 25.11).

Summary box 25.11

Types of brain injury

- Apparent traumatic subarachnoid haemorrhage may actually be a spontaneous subarachnoid haemorrhage which then led to the fall
- Diffuse axonal injury results from high energy injury
- Carotid dissection may be a delayed complication of skull base fracture
- Non-accidental injury in children: beware delayed presentation

Ongoing management: prevention of secondary injury

Following initial resuscitation and any emergency surgery required for systemic pathology and intracranial haematomas, the patient will require on-going management directed at minimizing secondary brain injury. This occurs in the minutes, hours and days following primary injury, as a result of factors summarised in Figure 25.9. Unlike the primary injury which describes the diffuse axonal injury and intracranial bleeding with which the patient presents, secondary injury is often preventable through avoidance of hypoxia and hypotension, and control of intracranial pressure. Unchecked, secondary injury leads to a further cycle of deterioration (see Figure 25.9).

The role of neurosurgical centres

Early discussion of patients and imaging with the regional neurosurgical service is advisable. UK Trauma Audit and Research Network data show higher mortality in patients with severe TBI

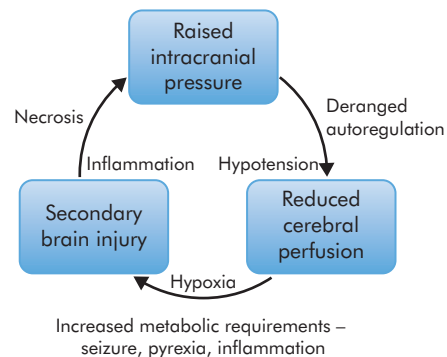

Figure 25.9 Brain swelling and mass lesions contribute to raised intracranial pressure, which compromises perfusion, leading to secondary brain injury and further swelling.

managed in non-neurosurgical centres, and this is reflected in NICE guidelines, which recommend early transfer irrespective of the need for surgery.

Control of intracranial pressure

Intubation and ventilation is required early in the management of severe brain injury for airway control. It is often required in moderate brain injury to facilitate the safe management and transfer of unstable and frequently agitated patients and in order to control intracranial pressure. Sedating the patient prevents clinical assessment of intracranial pressure by monitoring of GCS and focal neurological signs, leaving only pupil responses as a guide. It is therefore important that intracranial pressure monitoring is instituted as soon as possible to guide pressure management. This is typically achieved using a bolt ICP monitor, or else an external ventricular drain inserted into the lateral ventricle which also allows drainage of CSF for pressure control. The patient will need measurements of coagulation parameters, platelet count, and CT head available prior to insertion of the probe. A sustained rise of intracranial pressure over 20–25 mmHg is associated with a poor outcome, and maintenance of a cerebral perfusion pressure of at least 60 mmHg is important in preventing secondary injury.

The hierarchy of management strategies for controlling intracranial pressure is set out in Figure 25.10.

Initial measures

Initial measures include positioning the head up 20–30° (reverse Trendelenburg positioning by tilt of the whole bed if the spine has not been cleared). The cervical collar should be loose enough so that it does not restrict venous return. Ventilation is regulated to achieve normocapnia: hypocapnia may be used to achieve transient ICP control in the short term, but the cerebral vasoconstriction which results can produce hypoperfusion and eventual further secondary brain injury. Sedation using a combination of opiates and barbiturates at escalating doses and with boluses to coincide with turns and suctioning will assist in control (Table 25.4).

Friedrich Trendelenburg, 1844–1924, Professor of Surgery successively at Rostock (1875–1882), Bonn (1882–1895), Leipzig (1895–1911), Germany. The Trendelenburg position was first described in 1885.

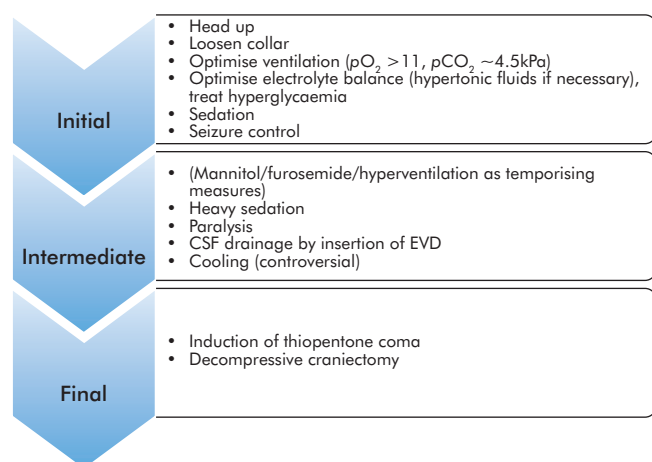

Figure 25.10 A hierarchy of intracranial pressure management strategies in ventilated head injury patients. CSF, cerebrospinal fluid; EVD, external ventricular drainage.

Table 25.4 Key parameters to maintain in head-injured patients on intensive care.

$pCO_2 = 4.5\text{--}5.0$ kPa
$pO_2 > 11$ kPa
MAP = 80–90 mmHg
ICP <20 mmHg
CPP >60 mmHg
[Na ⁺] >140 mmol/L
[K ⁺] >4 mmol/L

Intermediate measures

Where initial measures fail adequately to control ICP, sedation may be escalated and supplemented with paralysis. External ventricular CSF drainage represents a useful adjunct to physiological compensation.

Mannitol can be administered to control ICP temporarily. This is helpful where there is evidence of herniation, such as development of a dilated unresponsive pupil during transfer. 100 mL of 20 per cent mannitol is a typical bolus. Repeated or excessive use is counterproductive because it is an osmotic diuretic and produces hypovolaemia and hypotension. This will compromise cerebral perfusion. Administration of mannitol necessitates catheterising the patient to monitor fluid balance.

Pyrexia increases brain oxygen requirements and cell damage, and so should be avoided. Active induction of therapeutic hypothermia is effective in controlling intracranial pressure, but predisposes to complications including sepsis and coagulopathy so that its overall benefit is not firmly established.

Final measures

Decompressive craniectomy (Figure 25.11) involves removal of a portion of the skull vault and opening of the underlying dura, so that brain swelling can occur without the pressure increases predicted by the Monro Kellie doctrine. Generally, a unilateral or bifrontal decompressive craniectomy is performed, with the bone flap placed subcutaneously in the abdomen, then replaced (cranioplasty) weeks or months later.

Summary box 25.12

On-going management of significant head injury

- The patient should be intubated and ventilated with adequate sedation and pressure monitoring
- The goal of ongoing management is to minimise secondary brain injury
- Key parameters include oxygenation and ventilation, blood pressure and ICP, and electrolyte balance. Pyrexia should be actively controlled
- A hierarchy of management strategies exists to achieve control of intracranial pressure (Figure 25.10)

An alternative strategy for managing uncontrolled intracranial hypertension is induction of thiopentone coma. This carries a high risk of complications and results in the loss of normal EEG activity and pupil responses, compromising on-going evaluation of the patient.

A multicentre randomised control trial with the aim of establishing the relative effectiveness of these interventions, the Randomised Evaluation of Surgery with Craniectomy for Uncontrollable Elevation of Intra-Cranial Pressure (RESCUE-ICP), is underway (Summary box 25.12).

Pituitary dysfunction: endocrine and metabolic management

Electrolyte imbalance is common in TBI, and contributes to brain swelling and to causing seizures. Diverse mechanisms are involved. Cerebral salt wasting, a poorly understood form of excretory dysregulation in association with brain insult, leads to volume depletion and hyponatraemia. The syndrome of inappropriate antidiuretic hormone (SIADH) leads to water retention

Figure 25.11 Decompressive craniectomy. A right-sided decompressive craniectomy has been performed allowing the swollen right hemisphere to herniate through the skull defect. This procedure can help to control raised intracranial pressure. The bone flap can be stored and replaced at a later date.

and hyponatraemia in the context of pituitary damage. This is of particular concern in head injury since low serum osmotic pressure can contribute to brain swelling, so hypotonic fluids are avoided in this setting. Conversely, antidiuretic hormone (ADH) secretion may be compromised in the context of trauma, producing diabetes insipidus resulting in hypernatraemia. This may be managed with boluses of desmopressin in consultation with endocrine specialists.

All aspects of pituitary function may be compromised in the setting of TBI. Routine screening of pituitary hormone levels and liaison with endocrinology is an important aspect of optimal medical management.

Note that routine, rather than directed, administration of corticosteroids in severe head injury is associated with increased mortality and is not recommended.

Seizures

Seizures may occur early (within 7 days) or late. The cumulative probability is between 2 per cent (mild TBI) and 60 per cent (severe TBI with exacerbating features). Risk factors include injury severity, especially the presence of ICH, and depressed skull fractures and tears of the dura.

Antiepileptics, typically phenytoin, are administered prophylactically to patients at high risk of seizures.

Nutrition

Enteral nutrition is preferred to intravenous parenteral nutrition on grounds of cost and associated complications, and should be commenced within 72 hours of injury. Prokinetics (e.g. metaclopramide, erythromycin) can be administered to promote absorption (Summary box 25.13).

Summary box 25.13

Investigations and prophylactic measures in significant head injury

- Check pituitary function
- Do not give hypotonic fluids
- Monitor daily for electrolyte imbalance
- Antiepileptics can be used prophylactically
- Steroids should not be given routinely
- Enteral nutrition should be started within 72 hours

Outcomes and sequelae

Mild injury: concussion, second impact syndrome and postconcussive syndrome

Concussion is defined as alteration of consciousness as a result of closed head injury, but is generally used in describing mild head injury without imaging abnormalities: loss of consciousness at the time of injury is not a prerequisite. Key features include confusion and amnesia. The patient may be easily distractable, forgetful, slow to interact or emotionally labile. Gait disturbance and incoordination may be seen.

It is claimed that while symptomatic following a head injury, patients may be especially vulnerable to repeat impacts. It is proposed that in the context of disordered cerebral autoregulation, a second minor injury may trigger a form of malignant cerebral oedema refractory to treatment. Although the existence of the

syndrome is disputed, and it is certainly rare, it should be considered in advice to individuals engaged in sports or activities carrying a risk of further injury: symptomatic players should not return to play. After a very mild concussion, they should not play again that day; after a severe concussion, they should refrain for the rest of that season (see www.headinjury.com/sports.htm#guidelines).

Postconcussive syndrome is a loosely defined constellation of symptoms, persisting for a prolonged period after injury, and exacerbated in some patients by the potential for secondary gain (compensation). Patients may report somatic features, such as headache, dizziness and disorders of hearing and vision. They may also suffer a variety of neurocognitive and neuropsychological disturbances, including difficulty with concentration and recall, insomnia, emotional lability, fatigue, depression and personality change.

Moderate and severe injury

The long-term sequelae of significant brain injury are likely to include many of the somatic and neurocognitive problems described above, combined with the effect of deficits attributable directly to the primary and secondary injury sustained. Rehabilitation represents a complex and prolonged challenge, requiring multidisciplinary coordination. The Glasgow Outcome Score is used to quantify the degree of recovery achieved after head injury, especially for research purposes, and is detailed in Table 25.5. Good recovery implies independence and potential to return to work rather than a full return to previous capacity (Summary box 25.14).

Table 25.5 Glasgow Outcome Score (GOS).

Good recovery	5
Moderate disability	4
Severe disability	3
Persistent vegetative state	2
Dead	1

Summary box 25.14

Outcomes of a head injury

- Post-concussion syndrome gives persisting headaches and problems in concentrating
- Players concussed when playing sport should not return immediately to the field
- Good recovery is not necessarily a return to normal; it may be independent living

ANEURYSMAL SUBARACHNOID HAEMORRHAGE

‘Spontaneous’ aneurysmal subarachnoid haemorrhage (SAH) is due to the rupture of an aneurysm in about 80 per cent of cases. In addition to saccular aneurysms discussed below, aneurysms may develop due to infective infiltration of arterial walls in the context of bacteraemia (mycotic aneurysm). This may

occur following intravenous drug use or infective endocarditis. Pseudoaneurysms may also develop after trauma or after surgery.

Epidemiology

Berry aneurysms of the circle of Willis develop at branch points in the arterial tree associated with turbulent blood flow (Figure 25.12).

Aneurysmal bleeding has an incidence of 10–15 per 100 000 population per year. Risk factors include age, female sex, hypertension, smoking, cocaine abuse and a family history with two first-degree relatives affected. A range of genetic disorders, in particular adult polycystic kidney disease, fibromuscular dysplasia, neurofibromatosis type 1, Ehlers-Danlos and Marfan syndromes, are known to predispose patients to this condition.

Figure 25.12 Main sites of intracranial supraclinoid aneurysms.

Clinical features

Approximately one third of subarachnoid haemorrhages are incorrectly diagnosed at initial presentation. They are then at high risk of succumbing to early complications, especially a rebleed.

The typical presentation of a subarachnoid haemorrhage includes a 'thunderclap' headache, which is both sudden and severe and is outside the patient's normal experience. Some patients describe prodromal headaches preceding the event, potentially representing aneurysm growth or subclinical bleeds. The sudden onset occurs commonly but not exclusively during exertion, and may be associated with seizure (10 per cent), unresponsiveness (50 per cent) and vomiting (70 per cent). Sometimes it is difficult to establish whether SAH has caused a fall, or whether a fall with head injury is responsible for the SAH.

Neurological examination may be normal ('good clinical grade', see Table 25.6), or the patient may have focal deficits and an impaired conscious level ('poor grade'). The World Federation of Neurosurgical Societies (WFNS) grading of subarachnoid haemorrhage is measured against the condition of the patient after resuscitation rather than at the time of the onset of symptoms (ictus). Often patients are referred to as 'good grade' (WFNS 1–3) or 'poor grade' (WFNS 4 and 5) patients. A painful third nerve palsy points to compression from a posterior communicating artery aneurysm. Meningitic features of neck stiffness

and photophobia often develop over hours. Intraocular haemorrhages, classically subhyaloid, may be visible on fundoscopy. The combination of subarachnoid haemorrhage and vitreous haemorrhage is known as Terson syndrome and occurs in 15–20 per cent of patients. Papilloedema should be sought, but may not be evident early in the course of a developing hydrocephalus (Summary box 25.15).

Table 25.6 World Federation of Neurological Surgeons Grading of subarachnoid haemorrhage.

Grade	Glasgow Coma Scale	Focal deficits ^a
I	15	–
II	13–14	–
III	13–14	+
IV	7–12	±
V	3–9	±

^aFocal deficit = dysphasia or limb weakness.

Summary box 25.15

Subarachnoid haemorrhage

- Most develop from a saccular aneurysm
- They are most common at junctions of the circle of Willis
- Presentation is a thunderclap headache often during exertion
- If neurological examination is normal, the prognosis is good
- Computed tomography (CT) is the investigation of choice

Investigation

CT scan is the imaging of first choice, and, when performed within 12 hours of ictus, will confirm bleeding in more than 98 per cent of cases. This makes a diagnostic lumbar puncture unnecessary (Figure 25.13).

The sensitivity of CT scan, however, deteriorates to less than 50 per cent at 1 week after a bleed. In light of this, patients with a suggestive history and negative CT scan will require lumbar

Figure 25.13 Diffuse subarachnoid bleeding from a ruptured anterior communicating artery aneurysm extends to the prepontine and ambient cisterns around the brainstem, and into both Sylvian fissures.

puncture, especially where presentation is delayed. The CSF supernatant should be analysed by spectrophotometry (visual inspection is not reliable) for the spectra of haemoglobin breakdown products oxyhaemoglobin and bilirubin. These are clearly detectable in samples taken at least 6 and preferably 12 hours after subarachnoid haemorrhage, but not in CSF mixed with fresh blood due to traumatic puncture and analysed immediately. Failure to exclude subarachnoid haemorrhage with an appropriate delayed lumbar puncture may necessitate formal cerebral angiography, and the risks this entails.

Catheter angiography generally involves access to both vertebral and carotid arteries through the femoral artery under local anaesthetic. This allows visualisation of the vascular anatomy by injection of contrast medium with simultaneous x-ray screening (Figures 25.14 and 25.15). The serious potential risks include ischaemic stroke or arterial dissection (1–2 per cent), and renal failure or allergic reactions attributable to contrast.

Figure 25.14 There is a small saccular aneurysm of the pericallosal branch of the anterior cerebral artery.

Management

Patients should be placed on bed rest with hourly neurological observations. They require strict input–output monitoring and intravenous fluid replacement with normal saline initially. Oral nimodipine at a dose of 60 mg every 4 hours has been shown to reduce the rate of poor outcome associated with delayed neurological ischaemic deficit due to cerebral vasospasm. Analgesics, laxatives, antiemetics, gastric protection and compression stockings are also likely to be necessary. After resuscitation, the priorities in subarachnoid haemorrhage are:

- to prevent rebleeding by identifying and controlling any underlying lesion;
- to recognise and manage:
 - neurological complications, especially vasospasm (or delayed ischaemic neurologic deficit) and hydrocephalus;
 - systemic complications, including electrolyte imbalance, severe hypertension, cardiac infarct and arrhythmia, and neurogenic pulmonary oedema.

These goals are best served by early transfer of the patient to a neurosurgical centre. In elderly patients with a poor WFNS grade, a decision to offer only supportive management may be appropriate.

Figure 25.15 (a) A giant aneurysm of the internal carotid; (b) angiographic embolisation (coiling) of the giant aneurysm. Note the single displaced coil passing into the distal ICA (internal carotid artery) and then the MCA (middle cerebral artery).

Prevention of rebleed

CT angiography (CTA) has a high sensitivity for aneurysms and arteriovenous malformations (AVMs), but digital subtraction angiography (DSA) remains the gold standard.

Aneurysms demonstrated may be removed from the circulation surgically by craniotomy and ‘clipping’, or by endovascular embolization, also known as ‘coiling’. Sometimes, mesh stents may also be used to help secure the metal coils within the aneurysm sac as part of this procedure. Class 1 evidence suggesting a lower risk of poor outcomes, at least for small anterior circulation aneurysms, has driven the uptake of coiling. However, a surgical approach remains necessary or preferable in many cases. A rebleed risk of 4 per cent in the first 24 hours, then 1.5 per cent per day thereafter is quoted for aneurysms, and 80 per cent of patients who rebleed have an eventual poor outcome. For this reason, and to permit optimal management of complications discussed later, the current consensus favours early intervention, despite the surgical challenges presented by brain swelling and blood load (Summary box 25.16).

Identification and management of complications

After subarachnoid haemorrhage, even initially good grade patients may deteriorate rapidly due to reversible neurological

Summary box 25.16**Treatment of subarachnoid haemorrhage**

- Early securing of the responsible aneurysm reduces the risk of rebleed and is necessary for management of later vasospasm
- Endovascular treatment ('coiling') is generally preferred over craniotomy and clipping for aneurysms amenable to this approach
- 'Good grade' patients commonly suffer poor outcomes, primarily as a result of cerebral vasospasm

or systemic complications. They should be managed in a neurosurgical unit, and will require careful neurological observation, on a high dependency unit where possible. The approach to a patient who has deteriorated should follow standard principles of resuscitation, with consideration paid to the high incidence of electrolyte imbalance, cardiac infarcts and arrhythmias, and neurogenic pulmonary oedema in this group. Neurological deterioration should prompt a repeat scan to exclude evidence of rebleeding and of hydrocephalus. This is typically the communicating type, which is a common sequel of haemorrhage. Where these complications are not demonstrated, deterioration is often attributable to delayed ischaemic neurological deficit (DNID), which commonly develops 3–10 days after aneurysmal haemorrhage and can progress rapidly to infarction. The process is attributed to cerebral vasospasm in response to, and correlating with, the blood load. This process can be visualised angiographically, and the velocity of blood flow in the cerebral vasculature, measured using transcranial Doppler ultrasound (TCDs), provides an indirect assessment of the degree of stenosis. Outcomes are optimised by the prophylactic administration of nimodipine and maintenance of fluid volume, typically with 2.5–3 L/day of normal saline. In established vasospasm, the goal is to maintain cerebral perfusion. Practically this involves maintaining mean arterial pressure with aggressive fluid replacement and inotropes. This is done by the administration of fluid and inotropes. This strategy would risk rerupturing an unsecured underlying aneurysm, a factor weighing in favour of early clipping or coiling. Hyponatraemia is a frequent complication of subarachnoid haemorrhage, attributed to cerebral salt wasting in the context of fluid depletion, and otherwise to the syndrome of inappropriate antidiuretic hormone secretion. This is associated with a higher incidence of DNID, and practical management, irrespective of the underlying pathology, is based on sodium replacement, with hypertonic infusions if necessary. Fluid restriction is not appropriate in these patients since this risks further compromising perfusion (Summary box 25.17).

Prognosis

Overall survival of subarachnoid haemorrhage is about 50 per cent and one third of survivors remain dependent. Only 50 per cent of WFNS grade 1 patients return to work. Treated aneurysms can regrow and rebleed, especially after coiling, so that a program of surveillance is necessary.

A distinct subgroup of SAH patients suffer bleeds confined to the basal cisterns anterior to the midbrain and pons, without an underlying lesion evident on angiogram. This is termed

Summary box 25.17**Complications of subarachnoid haemorrhage**

- Electrolyte imbalance, cardiac arrhythmias and neurogenic pulmonary oedema are common
- Neurological deterioration may indicate a communicating hydrocephalus
- Delayed ischaemic neurological deficit (DNID) is attributed to vasospasm of the cerebral vasculature typically developing 3–10 days post ictus. It is the main cause of poor outcome in good grade subarachnoid patients
- After securing the aneurysm, perfusion can be maintained in the context of vasospasm by artificial elevation of the arterial blood pressure

'perimesencephalic SAH', and is believed to represent venous bleeding. It has an excellent prognosis.

Unruptured aneurysms represent a thorny management problem: incidentally detected small anterior circulation aneurysms represent a minimal bleeding risk. Screening, even in high risk groups, is therefore of questionable benefit.

OTHER SPONTANEOUS INTRACRANIAL HAEMORRHAGE**Intracerebral haemorrhage**

Intracerebral haemorrhage may be spontaneous or traumatic. The former accounts for a 10–15 per cent of strokes and has a mortality of 40 per cent at one year. The majority occur in the context of hypertension or amyloid angiopathy, or as a complication of ischaemic stroke. Coagulation disorders, especially patients being treated with warfarin, are a major risk factor (Summary box 25.18).

Summary box 25.18**Intracerebral haemorrhage**

- These account for 10–15 per cent of strokes
- The presentation, as for ischaemic stroke, may include focal neurological deficit with or without decreased conscious level
- High blood pressure may be chronic so should only be reduced with care
- Diagnosis is by computed tomography
- Anticoagulants should be reversed at once
- Craniotomy and evacuation is especially useful in young patients

Patients typically present with sudden focal deficit and reduced conscious level. Following initial resuscitation, these patients will require CT scan to establish the diagnosis, and the size and position of the bleed (Figure 25.16). They require reversal of anticoagulation, on-going hourly neurological observations and blood pressure monitoring. High blood pressure may be longstanding and associated with adaptations to autoregulation, so attempts at lowering it acutely with intravenous antihypertensives should be made only if the values are very high (e.g. MAP >130 mmHg).

Craniotomy and evacuation is used to alleviate raised intracranial pressure, just as it can be in a subgroup of patients with ischaemic strokes in the posterior fossa or in the middle cerebral artery territory. Surgery has no role in addressing focal deficits corresponding to direct damage from the bleed itself. Young patients with haematomas close to the cortical surface, demonstrating progressive neurological deterioration, represent good surgical candidates. Posterior fossa clot is also a strong indication for surgery because of the potential for rapid deterioration due to brainstem compression and hydrocephalus. A substantial minority of intracerebral bleeds are attributable to focal vascular lesions, and this must be considered when planning any surgery.

Vascular malformations

Vascular malformations are usually congenital in origin, with certain key exceptions discussed below. They may present with headaches, pulsatile tinnitus, seizures or focal deficit, or else acutely with rupture and haemorrhage.

Figure 25.16 Large acute intracerebral haemorrhages in the right frontal and parietal lobes are evident, with surrounding oedema and midline shift.

Figure 25.17 An arteriovenous malformation supplied by the anterior cerebral, middle cerebral and middle meningeal arteries is demonstrated at the 4 o'clock position in this angiogram.

Arteriovenous malformations are responsible for about 10 per cent of subarachnoid haemorrhages. Vessels and calcification may be apparent on CT or magnetic resonance imaging (MRI), and the lesion is confirmed on angiography (Figure 25.17).

When AVMs present with bleeding, there is an approximate 4 per cent risk of rebleed per annum. The risk is particularly high in the first 6 weeks, and where the bleed is from an aneurysm related to the AVM. This fact often weighs against treatment by radiosurgery, which typically takes more than one year to achieve complete occlusion, but may nevertheless be applied to some small, deep AVMs. Endovascular embolisation, with tissue glue, is often a useful first-line therapy, but carries significant risks and rarely achieves complete and permanent obliteration. Most patients will therefore ultimately require craniotomy, taking into account the risks of deficit associated with operation. These may be predicted using the Spetzler–Martin grading system, which is based on the size of the lesion, the eloquence of adjacent brain, and the pattern of venous drainage.

Vein of Galen malformations are AVMs feeding into an embryological venous remnant dorsal to the brainstem presenting in childhood. High-flow malformations may cause cardiac failure. They may be treated by embolisation.

Dural arteriovenous fistulae (DAVFs) are shunts between dural arteries and veins or sinuses. They are proposed to arise as a result of vessel remodelling in response to dural sinus thrombosis and subsequent recanalisation. They may present with subarachnoid, intracerebral or subdural bleeding, or with headache and pulsatile tinnitus. A carotid cavernous fistula is a spontaneous or traumatic DAVF between the internal carotid artery and surrounding cavernous sinus, typically producing eye pain, ocular muscle palsies and exophthalmos. Angiography is diagnostic.

Cavernomas (Figure 25.18) are venous anomalies, demonstrated on MRI, but not with angiography, which may require operation if they cause progressive deficits, intractable epilepsy or recurrent bleeding.

Figure 25.18 A brainstem cavernoma.

Related lesions, usually clinically silent, include developmental venous anomalies (DVAs) and capillary telangectasia.

SUMMARY

The guiding principle of management for neurosurgical emergencies is the prevention of secondary injury by ensuring satisfactory brain perfusion. This demands immediate attention to blood pressure and oxygenation, as reflected in the ATLS resuscitation algorithms, as well as intracranial pressure management. Early imaging to identify treatable pathology and timely discussion with the local Neurosurgery Centre are key to outcome.

LEARNING OBJECTIVES

To be familiar with:

- The accurate assessment of spinal trauma
- The pathophysiology and types of spinal cord injury
- The basic management of spinal trauma and the major pitfalls
- The prognosis of spinal cord injury, factors affecting functional outcome, and common associated complications

EPIDEMIOLOGY OF SPINAL CORD INJURY

The incidence of spinal cord injury ranges between 27 and 47 cases per million per year. Road traffic accidents remain the leading cause of spinal cord injuries worldwide. Males in the third decade of life are the most likely group to sustain serious spinal cord injury.

EVOLUTION OF THE MANAGEMENT OF SPINAL CORD INJURY

There is clear evidence to show that fewer complications, decreased length of stay, and improved patient outcome occur in patients treated in specialised spinal centres (Summary box 26.1).

Summary box 26.1

Spinal cord injury

- Incidence of spinal cord injury remains constant
- Outcome is improved in regional/national spinal cord injury centres

Figure 26.1 The spinal motion segment.

Figure 26.2 Ligamentous spinal restraints. (1) Anterior longitudinal ligament, (2) intervertebral disc and posterior longitudinal ligament, (3) facet joint capsule, (4) interspinous ligament, (5) supraspinous ligament.

ANATOMY OF THE SPINE AND SPINAL CORD

Spinal column anatomy

The vertebral column is composed of a series of motion segments (Figure 26.1). A motion segment consists of two adjacent vertebrae, their intervertebral disc and ligamentous restraints (Figure 26.2).

Regional variations

Upper cervical spine anatomy is designed to facilitate motion (Figure 26.3), and stability here is dependent on ligamentous restraints (Figure 26.4). Vertebral anatomy from C3 to C7 is similar. The cervicothoracic junction is a transitional zone from mobile to fixed and is thus prone to injury. It may be difficult to visualise this area on x-ray (Figure 26.5).

The thoracolumbar junction is also prone to injury and is the most common area of injury outside the cervical spine (Figure 26.6).

Figure 26.3 Atlantoaxial bony anatomy.

Figure 26.4 Atlantoaxial ligaments.

The three column concept of spinal stability

The spinal column can be divided into three columns: anterior, middle and posterior (Figure 26.7). When all three columns are injured the spine is unstable. Instability may also exist in some two-column injuries (Summary box 26.2).

Summary box 26.2

Spinal column anatomy

- Upper cervical spine stability is dependent on ligamentous restraints
- The cervicothoracic and thoracolumbar junctions are prone to injury

Figure 26.5 Cervicothoracic facet subluxation (easily missed with inadequate x-rays).

Figure 26.6 Coronal T2-weighted magnetic resonance image demonstrating a fracture dislocation at the thoracolumbar junction.

Spinal neuroanatomy

The spinal cord extends from the foramen magnum to the T12/L1 junction where it ends as the conus medullaris (Figure 26.8). Below this level lies the cauda equina. Figure 26.9 illustrates a cross-section of the spinal cord. The lateral spinothalamic tracts transmit the sensation of pain and temperature, the lateral corticospinal tracts are responsible for motor function, and the posterior columns transmit, position, vibration and deep pressure sensation.

Figure 26.7 The three-column model of spinal stability.

Figure 26.8 The spinal cord ends at T12/L1 at the conus medullaris which gives rise to the cauda equina.

Figure 26.9 A cross-section of the spinal cord.

The spinothalamic tracts cross to the opposite side of the spinal cord within three levels of entering the cord. In contrast, the corticospinal tracts and the posterior columns decussate proximally at the craniocervical level. The tracts are topographi-

cally arranged; proximal body function is represented centrally with distal body function arranged peripherally.

Pathophysiology of spinal cord injury

The primary injury

This is the direct insult to the neural elements and occurs at the time of the initial injury.

The secondary injury

Haemorrhage, oedema and ischaemia results in a biochemical cascade that causes the secondary injury. This may be accentuated by hypotension, hypoxia, spinal instability and/or persistent compression of the neural elements. Management of a spinal cord injury must focus on minimising secondary injury (Summary box 26.3).

Summary box 26.3

Pathophysiology of spinal cord injury

- The spinal cord contains various tracts that are topographically arranged
- Spinal cord injury involves both primary and secondary phases
- Therapeutic strategies are directed at reducing the secondary injury

PATIENT ASSESSMENT

Basic points

Advanced Trauma Life Support (ATLS) principles apply in all cases (Chapter 23). The spine should initially be immobilised on the assumption that every trauma patient has a spinal injury until proven otherwise (Figure 26.10). The finding of a spinal injury makes it more likely (not less) that there will be a second injury at another level.

Spinal boards lead to skin breakdown in insensate patients, and are very uncomfortable for those with normal sensation. Therefore, they are for very short-term use only (Figure 26.11).

The unconscious patient

Definitive clearance of the spine may not be possible in the initial stages and spinal immobilisation should then be maintained, until magnetic resonance imaging (MRI) or equivalent can be used to rule out an unstable spinal injury (Summary box 26.4).

Figure 26.10 Spinal immobilisation.

Figure 26.11 Pressure sores and ulcers may develop rapidly in insensate patients.

Summary box 26.4

Patient assessment

- Use Advanced Trauma Life Support (ATLS) principles in all cases of spinal injury
- In polytrauma cases, suspect a spinal injury
- A second spinal injury at a remote level may be present in 10 per cent of cases
- Spinal boards cause pressure sores

PERTINENT HISTORY

The mechanism and velocity of injury should be determined at an early stage. A check for the presence of spinal pain should be made. The onset and duration of neurological symptoms should also be recorded.

PHYSICAL EXAMINATION

Initial assessment

The primary survey always takes precedence, followed by careful systems examination, paying particular attention to the abdomen and chest. Spinal cord injury may mask signs of intra-abdominal injury.

Identification of shock

Three categories of shock may occur in spinal trauma:

- 1 **Hypovolaemic shock.** Hypotension with tachycardia and cold clammy peripheries. This is most often due to haemorrhage. It should be treated with appropriate resuscitation.
- 2 **Neurogenic shock.** This presents with hypotension, a normal heart rate or bradycardia and warm peripheries. This is due to unopposed vagal tone resulting from cervical spinal cord injury above the level of sympathetic outflow (C7/T1). It should be treated with inotropic support, and care should be taken to avoid fluid overload.
- 3 **Spinal shock.** There is initial loss of all neurological function below the level of the injury. It is characterised by paralysis, hypotonia and areflexia. It usually lasts 24 hours following spinal cord injury. Once it has resolved the bulbocavernosus reflex (Figure 26.12) returns.

Spinal examination

The entire spine must be palpated and the overlying skin inspected. A formal spinal log roll must be performed to achieve this (Figure 26.13). Significant swelling, tenderness, palpable steps or gaps suggest a spinal injury. Wounds may be part of penetrating trauma. Seat belt marks on the abdomen and chest must be noted, as these suggest a high energy accident.

Figure 26.12 The bulbocavernosus reflex (this can be elicited in females by traction on the Foley catheter).

Figure 26.13 Spinal log roll.

Neurological examination

The American Spinal Injury Association (ASIA) neurological evaluation system (Figure 26.14) is an internationally accepted method of neurological evaluation.

Motor function is assessed using the Medical Research Council (MRC) grading system (0–5) in key muscle groups (Figure 26.14). A motor score can then be calculated (maximum 100).

Sensory function (light touch and pin prick) is assessed using the dermatomal map (Figure 26.14). A total sensory score is then calculated.

Rectal examination is performed to assess anal tone, voluntary anal contraction and perianal sensation.

Level of neurological injury

The level of neurological injury is simply the most caudal neurological level with normal neurological function.

Complete versus incomplete spinal cord injury

A spinal cord injury is incomplete when there is preservation of perianal sensation.

Type of incomplete spinal cord injury

There are several types of incomplete spinal cord injuries. These include: central cord syndrome, Brown-Séquard syndrome (hemisection), anterior spinal syndrome, posterior cord syndrome and cauda equina syndrome.

Charles Edward Brown-Séquard, 1817–1894, was a physiologist and neurologist who held a number of academic posts. He came from Mauritius and in his dotage reported enhanced sexual prowess after treating himself with extract of monkey testis. Some therefore think of him as the father of endocrinology.

Level of neurological impairment

The ASIA neurological impairment scale is based on the Frankel classification of spinal cord injury:

- A, complete;
- B, sensation present motor absent;
- C, sensation present, motor present but not useful (MRC grade <3/5);
- D, sensation present, motor useful (MRC grade ≥3/5);
- E, normal function (Summary box 26.5).

Summary box 26.5

Physical examination

- There are three types of shock following spinal cord injury
- The ASIA neurological scoring system should be used
- Functional motor power is grade 3/5 or higher

DIAGNOSTIC IMAGING

Plain radiographs

A full cervical spine series includes anteroposterior and lateral views of the whole cervical spine, and open mouth views. However, in many trauma centres computed tomography (CT) scanning, with sagittal reformats, is considered more accurate. This modality is particularly useful in visualising the cervicothoracic junction and in surveying the entire spine.

A system for evaluation of the lateral cervical spine x-ray

- 1 Assessment of prevertebral soft tissue swelling (Figure 26.15)
- 2 Assess sagittal alignment using three imaginary lines (Figure 26.16)
- 3 Assess for instability (Figure 26.17):
 - a 3.5 mm of sagittal translation;
 - b Sagittal angulation of >11° (compared to adjacent level).

Computed tomography

CT scanning with two-dimensional reconstruction remains the most sensitive imaging modality in spinal trauma (Figure 26.18).

Magnetic resonance imaging

MRI is indicated in cases with neurological deficit and where assessment of ligamentous structures is important (Figure 26.19) (Summary box 26.6).

Summary box 26.6

Diagnostic imaging of spinal injuries

- Clear visualisation of the cervicothoracic junction is mandatory
- Plain cervical spine radiographs fail to identify 15 per cent of injuries

CLASSIFICATION AND MANAGEMENT OF SPINAL AND SPINAL CORD INJURIES

Basic management principles

Spinal realignment

In cases of cervical spine subluxation or dislocation, skeletal traction is necessary to achieve anatomical realignment. This is done using skull tongs (Figure 26.20).

In many cases of spinal trauma, formal open reduction and stabilisation using internal fixation is also required (Figure 26.21).

A halo brace can be used to hold a closed realignment of cervical fractures (Figure 26.22).

Stabilisation

The indication for operative intervention is influenced by the injury pattern, degree of instability and the presence of a neurological deficit. The only absolute indication for surgery in spinal trauma is deteriorating neurological function.

Figure 26.21 (a) Thoracolumbar fracture dislocation; (b) treated with open reduction and posterior fixation; (c) bifacet cervical spine dislocation; (d) posterior stabilisation following closed reduction.

Decompression of the neural elements

Decompression involves spinal realignment and/or direct decompression of the neural elements (Figure 26.23). The timing of surgery in spinal cord trauma remains controversial.

Corticosteroids

Many spinal trauma centres no longer use steroids in cases of spinal cord injury due to lack of evidence to support efficacy (Summary box 26.7).

Summary box 26.7

Management of spinal trauma

- Neurological deficit determines management
- Deteriorating neurological status requires surgical intervention
- Corticosteroids are ineffective

Figure 26.22 External immobilisation using a halo jacket.

SPECIFIC SPINAL INJURIES

Upper cervical spine (skull–C2)

Craniocervical dislocation

This injury is usually caused by high energy trauma and is often fatal. The dislocation may be anterior, posterior or vertical (Figure 26.24). Power's ratio (Figure 26.25) is used to assess skull translation.

Atlantoaxial instability

This is uncommon and either resolves spontaneously or with traction. Isolated, traumatic transverse ligament rupture leading to C1/2 instability is uncommon and is treated with posterior C1/2 fusion (Figure 26.26).

Occipital condyle fracture

This is a stable injury often associated with head injuries, and is best treated in a hard collar for 8 weeks.

Figure 26.23 (a) Sagittal T2-weighted magnetic resonance image showing an L1 burst fracture and neural compression; (b) treated with combined anterior and posterior surgery.

Jefferson fractures (C1 ring)

These injuries are associated with axial loading of the cervical spine and may be stable or unstable (Figure 26.27a). Associated

Sir Geoffrey Jefferson, 1886–1961, Professor of Neurosurgery, University of Manchester, UK. He became the UK's first Professor of Neurosurgery in 1939. In 1947, he was elected a Fellow of The Royal Society, a rare distinction for a practising surgeon. Although he became a neurosurgeon, he performed the first successful embolectomy in England in 1925 at Salford Royal Hospital.

Figure 26.24 Vertical occipitocervical dislocation.

Figure 26.25 Power's ratio. $BC/OA \geq 1$ indicates anterior translation, ≤ 0.75 indicates posterior translation.

transverse ligament rupture may occur (Figure 26.27b). Most are treated non-operatively in a collar or halo brace.

Odontoid fractures

There are three types of Odontoid peg fracture (Figure 26.28). Neurological injury is rare. The majority of acute injuries are treated non-operatively in a halo jacket or hard collar for three months. Internal fixation with an anterior compression screw is indicated in displaced fractures (Figure 26.29).

Posterior C1/2 fusion is required in cases of non-union.

Hangman's fracture

The Hangman's fracture is a traumatic spondylolisthesis of C2 on C3. There are four types with varying degrees of instability (Figure 26.30). Those with significant displacement or associ-

Figure 26.26 (a) Atlantoaxial subluxation. (b) C1/2 posterior fusion using C1 lateral mass and C2 pedicle screws.

ated facet dislocation are treated operatively, usually with posterior stabilisation.

Subaxial cervical spine (C3–C7)

The pattern of lower cervical spine injury depends on the mechanism of trauma. These include wedge (hyperflexion), burst (axial compression), tear-drop fractures (hyperextension) and facet subluxation/dislocation (rotation and hyperflexion). The more severe injuries are accompanied by spinal cord injury (Figure 26.31a). Operative intervention may be required to decompress the spinal cord and stabilize the spine with internal fixation (Figure 26.31b).

Facet subluxation/dislocation ranges in severity from minor instability to complete dislocation with spinal cord injury (Figure 26.32) (Summary box 26.8).

Figure 26.27 Stable (a) versus unstable (b) Jefferson's fracture of C1. Open mouth view of C1/2 demonstrating C1 lateral mass deviation. Rupture of the transverse ligament is present when the combined lateral mass deviation exceeds 6.9 mm.

Figure 26.28 Types of odontoid fracture.

Thoracic and thoracolumbar fractures

The system developed by the AO (*Arbeitsgemeinschaft für Osteosynthesefragen*) can be used to classify these fractures. There are three main injury types (A, B and C) with increasing instability and risk of neurological injury. Type A fractures involve the vertebral body. Type B injuries have additional distraction/disruption of the posterior elements and type C injuries are

Figure 26.29 Type II odontoid fracture. Treated with an anterior compression screw.

Summary box 26.8

Cervical spine injuries

- The majority of upper cervical spinal injuries are treated non-operatively
- Spinal cord injury is more commonly associated with subaxial cervical spinal injuries

rotational. The majority of type B and type C injuries require surgical stabilization.

Thoracic spine (T1–T10)

Osteoporotic wedge compression fractures in the elderly are the most common injury in this group. Symptomatic fractures can be treated with percutaneous bone cement augmentation, known as vertebroplasty or kyphoplasty (Figure 26.33).

In trauma cases, unstable fractures are associated with significant energy transfer to the patient and may be associated with major internal injuries, such as pulmonary contusion and spinal cord injury. The combination of thoracic spine disruption and

Figure 26.30 (a) Hangman's fractures of C2 with minimal forward translation. (b) C2/3 subluxation with spinal cord contusion.

Figure 26.31 (a) Cervical burst fracture with spinal cord contusion. (b) Treated by anterior decompression and reconstruction.

Figure 26.32 C5/6 bifacetal dislocation.

a sternal fracture (Figure 26.34) also carries a significant risk of aortic rupture. Multiple posterior rib fractures and rib dislocations above and below a thoracic spinal injury signify a major rotational injury to the chest and are associated with vascular injury and significant pulmonary contusion (Figure 26.35).

Multimodality diagnostic imaging is recommended. Surgery is appropriate in almost all unstable thoracic injuries.

Thoracolumbar spinal fractures (T11–S1)

The thoracolumbar junction is especially prone to injury. This can vary from a minor wedge fracture to spinal dislocation (Figure 26.36). Burst fractures are comminuted fractures of the vertebral body. Usually the distance between the pedicles is widened and bone fragments are retropulsed into the spinal canal (Figure 26.37). The surgical approach can be anterior, posterior or combined. For burst fractures with neurological compromise, an anterior approach with vertebral corpectomy, canal clearance and anterior reconstruction (Figure 26.38) is often used.

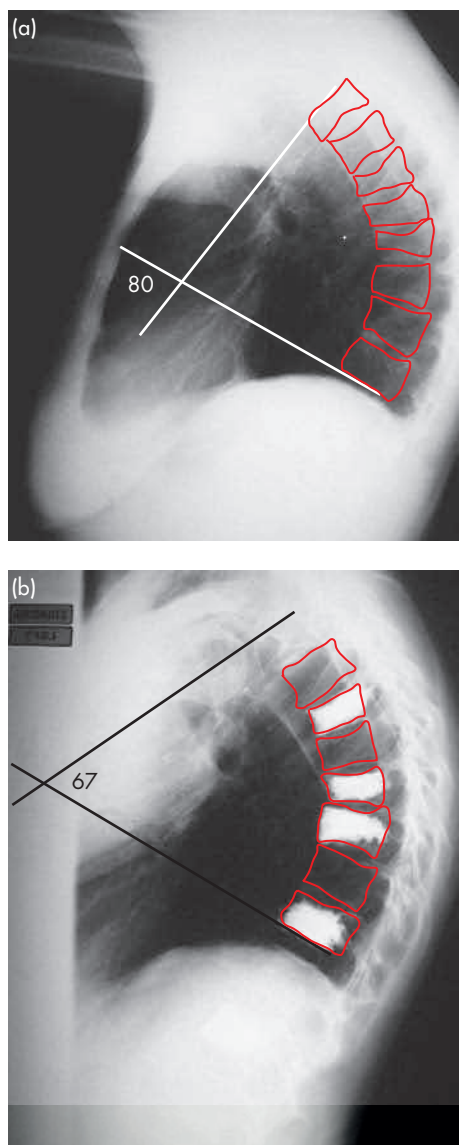

Figure 26.33 (a) Lateral x-ray showing multiple osteoporotic compression fractures. (b) Reduction in thoracic kyphotic deformity following four level kyphoplasty.

Figure 26.34 Sagittal computed tomographic reconstruction showing an upper thoracic spine fracture dislocation and associated sternal fracture.

Figure 26.36 Total spinal sagittal computed tomographic reconstruction demonstrating a thoracolumbar fracture dislocation and fracture of L5.

Chance fractures are flexion–distraction injuries of the thoracolumbar junction and are classically associated with the use of lap belts (Figure 26.39). Duodenal, pancreatic and/or aortic rupture, are also associated with these injuries (Summary box 26.9).

Summary box 26.9

Thoracic and thoracolumbar fractures

- Unstable thoracic spine fractures and thoracolumbar flexion–distraction injuries are commonly associated with vascular and/or visceral injuries

Figure 26.37 Lumbar burst fracture with increase in interpedicular distance (a) and spinal canal compromise (b).

Figure 26.38 Anterior spinal reconstruction for a lumbar burst fracture.

REHABILITATION AND PATIENT OUTCOME

The goal of spinal cord injury rehabilitation focuses on maximising the remaining neurological function. The level of neurological impairment determines functional outcome (Table 26.1).

Prognosis of spinal cord injury

Despite continuing improvements in patient care, life expectancy remains reduced (Table 26.2).

The prognosis for neurological recovery is strongly influenced by the pattern of initial injury, the completeness of the cord injury and the age at the time of injury.

Complications associated with spinal cord injury

Pain and spasticity

Neurogenic pain is common. Once reflex activity returns following cord injury, spasticity may occur and can be problematic.

Figure 26.39 A bony Chance fracture at the thoracolumbar junction secondary to a lap belt injury.

Table 26.1 Expected functional outcome versus level of cervical spinal cord injury.

Level of Injury	Functional goal
C3–C4	Power wheelchair with mouth or chin control. Verbalise care, communicate through adaptive equipment. May be ventilator dependent
C5	Power wheelchair, dress upper body, self-feed with aids, wash face with assistance
C6	Propel power wheelchair, possibly push manual wheelchair, transfer with assistance, dress upper body (lower body with assistance), self-groom with aids, bladder/bowel care with assistance, self-feed with splints, able to drive
C7	Manual wheelchair, independent transfer, dressing (with aids), feeding, bathing, self-care. Bladder and bowel care with assistance
C8–T4	Independent with most activities of daily living, and bowel and bladder care
T5–T12	As above, but with more ease. Independent with all self-care
L1–L5	Independent. Walk with short or long leg braces
S1–S5	Independent, able to walk if able to push off (S1) (may need brace). Bladder, bowel and sexual function may remain compromised

Table 26.2 Life expectancy (years) for post-injury by severity of injury and age at injury.

Age at injury	No SCI	Motor functional at any level	Para	Low tetra (C5–C8)	High tetra (C1–C4)	Ventilator-dependent at any level
(a) For people who survive the first 24 hours						
20	58.4	52.8	45.6	40.6	36.1	16.6
40	39.5	34.3	28.0	23.8	20.2	7.1
60	22.2	17.9	13.1	10.2	7.9	1.4
(b) For people surviving at least one year post-injury						
20	58.4	53.3	46.3	41.7	37.9	23.3
40	39.5	34.8	28.6	24.7	21.6	11.1
60	22.2	18.3	13.5	10.8	8.8	3.1

SCI, spinal cord injury.

Intrathecal infusion of baclofen may be required in resistant cases.

Autonomic dysreflexia

This is a paroxysmal syndrome of hypertension, hypohydrosis (above level of injury), bradycardia, flushing and headache in response to noxious visceral and other stimuli. It is most commonly triggered by bladder distension or rectal loading from faecal impaction.

Neurological deterioration

Post-traumatic syringomyelia may cause late (>3 months post-injury) neurological deterioration and occurs in 3–5 per cent of spinal cord injury cases. Increase in pain and/or spasticity, ascending loss of sensation and deep tendon reflexes are suspicious and warrant early MRI assessment. Expanding cavities require neurosurgical intervention.

Thromboembolic events

Deep vein thrombosis (DVT) occurs in 30 per cent of spinal cord-injured patients. Fatal pulmonary embolus is reported in 1–2 per cent of cases. Therefore, prophylaxis with low molecular heparin is recommended.

Osteoporosis, heterotopic ossification and contractures

Disuse osteoporosis is an inevitable consequence of spinal cord injury, and fragility fractures may occur. Heterotopic ossification may affect hips, knees, shoulders and elbows. It occurs in 25 per cent of spinal cord-injured patients. Surgery is appropriate in selected cases. Soft tissue contractures around joints may occur due to spasticity, but can be avoided by appropriate physical therapy, positioning and splinting.

LEARNING OBJECTIVES

To be able to:

- Recognise the life-threatening nature of facial injuries through compromise of the airway and associated head and spinal injuries

To have:

- A methodology for examining facial injuries

To know:

- The classification of facial fractures

To understand:

- The diagnosis and management of fractures of the middle third of the facial skeleton and the mandible

To appreciate:

- The importance of careful cleaning and accurate suturing of facial lacerations

INTRODUCTION

An unscarred face is important to the well-being of the individual, and thus all injuries, however trivial, should be treated thoughtfully and sympathetically, with every effort made to produce an optimal outcome. In addition, even trivial blows to the face may:

- cause injuries which compromise the airway;
- directly or indirectly cause a head injury;
- cause injuries to the cervical spine.

EPIDEMIOLOGY

Injuries to the orofacial soft tissues and facial skeleton commonly result from sporting activities, accidents and intentional violence.

There is significant variation in the aetiological causes of orofacial injuries in different parts of the world and this affects their incidence:

- **Social factors.** Interpersonal violence has steadily increased and in many countries is now the most common cause of orofacial injuries. This increase is noticed to a greater extent in conurbations and urban areas. It is often fuelled by alcohol excess.
- **Climatic factors.** The arrival of snow and freezing weather during the winter, and increased traffic volume and interpersonal violence during the warmer months of the year often produce seasonal variations in the incidence of injuries.
- **Road traffic accidents.** Legislation and improved vehicular design have lessened the number of injuries presenting as a result of road traffic accidents. Air bag provision, seat belts, laminated windscreens and drink/drive laws have all helped in reducing orofacial injuries in the developed world.

However, the enforcing of lower speed limits has not, as yet, been shown to reduce injuries.

CLINICAL EFFECTS

The mouth and nasal passages form part of the upper aerodigestive tract. Lacerations and fractures of the facial skeleton may give rise to immediate or delayed respiratory obstruction. Immediate obstruction may arise from inhalation of tooth fragments, accumulation of blood and secretions, and loss of control of the tongue in the unconscious or semiconscious patient. Patients with facial injuries should not be allowed to lie supine. They should be nursed in the semiprone position (Figure 27.1) with the head supported on the bent arm. Damaged teeth, blood and secretions can then fall out of the mouth and gravity pulls the tongue forward. As the patient is manoeuvred into the correct nursing position, the neck should be supported and held in a neutral position – a protective collar is advisable until a fracture of the cervical spine has been excluded. An intracranial injury should always be considered as a possibility, however minor the injury to the face.

Figure 27.1 The patient should be nursed in the semiprone position to allow secretions, blood and foreign bodies to fall from the mouth.

Initial haemorrhage after a facial injury can be dramatic, but sustained bleeding is unusual. The most likely cause of circulatory failure in a facial injury is the accompanying skeletal fractures or a ruptured viscus. These should always be actively sought in the shocked patient.

Oedema is a particular feature of all fractures of the facial skeleton and tends to develop within 60–90 minutes. Thus, a patient with a shattered face may appear to have a good airway immediately after the injury, but then swelling of the tongue, facial and pharyngeal tissues may then cause respiratory compromise. This is especially important when the middle third of the face is involved. In Le Fort III fractures (see below under The middle third), the maxilla may be thrust downwards and backwards along the base of the skull. As it does so, the posterior teeth of the upper and lower jaws contact prematurely and the mouth is held open (Figure 27.2) giving the impression of a good airway. However, as oedema develops, the soft palate and tongue may swell to meet, and close the pharyngeal airway. This leads to respiratory distress and even obstruction (Figure 27.3) (Summary box 27.1).

Summary box 27.1

Facial injuries

- Are potentially life-threatening
- May be associated with injuries to the brain and cervical spine
- Are cosmetically very important

EXAMINATION OF THE PATIENT

It is easy to be distracted from examining the whole patient by the dramatic appearance of a facial injury. The rapid onset of oedema may make examination of the face and routine head injury observations difficult – for instance, it may prove impossible to prise the eyelids apart to examine the pupils.

Once the pattern and extent of soft tissue injury have been established and recorded, attention should be directed towards

Figure 27.2 A blow from the front of the face may separate the facial skeleton from the base of the skull and thrust it downwards and backwards.

Figure 27.3 Loss of nasopharyngeal space and odema of the soft palate and tongue may close off the airway in severe maxillofacial injuries, 2–3 hours after injury.

the hard tissues. Regardless of the apparent site of the injury, the whole head should be examined visually and by palpation starting with the vault of the skull. The face should be examined from in front. Any asymmetry should be noted, although oedema may make this difficult. Gentle palpation gives the most information in searching for step deformities. Tenderness over sites of known weakness and potential for fracture (see below under Fractures of the facial skeleton) is a very good guide to the possibility of there being an underlying fracture. A good system is to examine from above downwards – checking first the supraorbital and infraorbital ridges, the nasal bridge and then the zygomas, including the arches. The mandible should then be examined starting at the condyles bilaterally and then following the posterior and lower border of the mandible as far as the midline. The majority of middle third injuries are accompanied by some degree of epistaxis (except isolated zygomatic arch fractures) and Le Fort II and III injuries frequently have a cerebrospinal fluid (CSF) leak with CSF rhinorrhoea. A particularly useful sign in the fractured zygoma is the frequent subconjunctival haemorrhage, which will often be found to have no posterior limit when the patient is asked to look to the other side (Figure 27.4).

The patient should then be examined intraorally with good illumination, taking note of the occlusion. The maxillary and mandibular dentition normally ‘fit’ together even if the occlu-

Figure 27.4 Fractures of the zygoma may often be associated with subconjunctival haemorrhage. This example shows no posterior border to the haemorrhage as the patient looks away from the side of the fracture.

sion is naturally irregular – if they do not, a fracture of the jaws may be suspected. All fractures involving the alveolus (the tooth-bearing portion of the jaw in the dentate patient) tear the gingivae and are compound into the mouth (Figure 27.5). A haematoma in the floor of the mouth is an indication of a fracture of the mandible, particularly in patients with no teeth of their own. The alignment of the teeth should be noted and any missing or broken teeth and dental restorations/prostheses should be carefully recorded. The occlusal plane must be examined for the presence of step defects. These indicate a likely fracture of the underlying bone. The patient should be asked to bring the teeth together, so that any occlusal anomalies may be observed. In some cases, independent movement of the fragments may also be detected. Jaw movement should be tested: deviation from the midline at rest or on opening suggests a fracture of the side to which the jaw is deviating.

If a fracture of the maxilla is suspected, then the maxillary dental arch should be grasped between the index finger and thumb of one hand in the incisor region, while the other is

Figure 27.5 A fracture of the right parasymphysis of the mandible, demonstrating a tear of the gingivae in the lower right lateral incisor/canine region.

placed on the forehead. If the maxilla is fractured, gentle pressure forward and backward, or side to side, will reveal movement between the examining hands. With the mandible, gentle manipulation across the suspected site of a fracture will produce 'springing' if a fracture is present.

Lacerations of the oral mucosa may occur independently of hard tissue injuries, and can often involve the buccal mucous membrane and tongue. Degloving lacerations most commonly involve the labial sulcus and the body of the mandible. Tongue injuries require careful assessment, as the depth of lacerations is often underestimated and may be a source for significant haemorrhage, which may be delayed. Palatal lacerations tend to occur in young children who fall on to objects held in the oral cavity, especially pens and pencils. With such a history, the possibility of a retained foreign body must be considered.

Checking for intact nerves

Paraesthesia suggests a fracture proximally along the course of the nerve. Thus, paraesthesia of the cheek and upper lip suggests a fracture involving the infraorbital foramen or floor of the orbit, while paraesthesia of the lower lip suggests a fracture of the mandibular body. Facial palsy may indicate damage to the branches of the facial nerve involved in facial lacerations. This is common in penetrating wounds of the parotid gland. In the absence of lacerations, facial palsy may indicate a fractured temporal bone.

Check visual acuity in both eyes. This may be difficult in the oedematous patient with marked periorbital oedema, but a pen torch shone directly through the lids will confirm gross optic nerve function. Where possible, pupil size and reflexes to light should be observed and recorded, as should eye movements. Check for diplopia by asking the patient to follow the light of a pen torch through a full range. Diplopia can occur with damage to the thin orbital plates of bone, particularly the floor of the orbit or from damage to the III, IV or VI cranial nerves.

All findings should be recorded accurately, preferably with diagrams to include measurements of lacerations, abrasions and areas of tissue loss. Photographs of the initial injury can be very helpful if litigation is likely to follow (Summary box 27.2).

Summary box 27.2

Examination of facial injuries

- Commence with lacerations and soft tissue injuries
- Systematically examine bones, including the occiput and cranial vault
- Check dental occlusion and palpate the mouth
- Examine cranial nerves

ADDITIONAL INVESTIGATIONS

Radiological investigations

Table 27.1 demonstrates the regularly used radiographic views utilised in the diagnosis of maxillofacial injuries. Coronal computed tomography (CT) scanning has superseded tomographic views in the diagnosis of orbital floor fractures, and coronal and axial CT scanning is often the choice of radiographic investigation in the more complex middle third fractures (Figure 27.6). A chest radiograph is indicated if there is any suggestion of inhalation of dental fragments or dental prostheses. It should be

Table 27.1 Radiological views for specific fractures.

Site of fracture	Radiographs
Mandible: body and ramus	OPT, lateral obliques, lower occlusal, PA mandible
Mandible: condyles	OPT, PA mandible with mouth open, Toller transpharyngeal views
Maxilla	OM 15° and 30°, lateral facial bones
Zygomatic complex	OM 15° and 30°, submentovertex
Orbital blow-outs	OM 15° and 30° and tomograms
Nasal bones	Lateral nasal bones, occipitofrontal
Frontal bones	Lateral skull, occipitofrontal

OM, posteroanterioroccipitontal; OPT, orthopantomogram; PA posteroanterior.

Figure 27.6 Computed tomographic (CT) scan showing a comminuted fracture of the right maxilla and zygomatic complex (nasal pack in place).

remembered, however, that polymethylmethacrylate (PMMA) used in the construction of dentures is not radiopaque and so may not be visible on plain radiographs.

Posteroanterior occipitontal radiographs are the optimum initial radiographs to illustrate the site and displacement of a middle third fracture. A panoramic oral radiograph, or ortho-

pantomogram (Figure 27.7), is the radiograph of choice for the mandible as it shows the whole bone from condyle to condyle.

FRACTURES OF THE FACIAL SKELETON

Fractures of the facial skeleton may be divided into those of the upper third (above the eyebrows), the middle third (above the mouth) and the lower third (the mandible). Fractures tend to occur through points of weakness – the sutures and foramina – and in thin unsupported bone.

The upper third

The patterns of fracture of the skull tend to be related to the site and type of trauma (sharp or blunt), but there are points of weakness in the skull, mainly involving the frontal sinuses and the supraorbital ridges.

The middle third

In 1911, Rene Le Fort classified fractures according to patterns which he created on cadavers using various degrees of force. The Le Fort classification is still used extensively today (Figure 27.8).

The **Le Fort I** fracture effectively separates the alveolus and palate from the facial skeleton above. The fracture line runs through points of weakness from the nasal piriform aperture, through the lateral and medial walls of the maxillary sinus, running posteriorly to include the lower part of the pterygoid plates.

The **Le Fort II** fracture is pyramidal in shape. The fracture involves the orbit, running through the bridge of the nose and the ethmoids whose cribriform plate may be fractured. It continues to the medial part of the infraorbital rim and often through the infraorbital foramen. It continues posteriorly to the pterygoid plates at the back through the lateral wall of the maxillary antrum at a higher level than the **Le Fort I**.

The **Le Fort III** fracture effectively separates the facial skeleton from the base of the skull – the fracture lines run high through the nasal bridge, septum and ethmoids. This creates the potential for dural tear and CSF leak. It then passes irregularly through the bones of the orbit to the frontozygomatic suture. The zygomatic arch fractures and the facial skeleton are separated from the bones above at a high level through the lateral wall of the maxillary sinus and the pterygoid plates.

The Le Fort fractures are seldom confined exactly to the original classification and combinations of any of the above fractures may occur.

Figure 27.7 An orthopantomogram demonstrating a fracture of the left angle of the mandible.

Figure 27.8 Maxillary fractures as classified by Le Fort. (a) Le Fort I; (b) Le Fort II; (c) Le Fort III.

Fracture of the zygomatic complex

This is the most common fracture of the middle third of the face, apart from the nose. The fractures occur through points of weakness: the infraorbital margin, the frontozygomatic suture, the zygomatic arch and the anterior and lateral wall of the maxillary sinus. Tears of the antral mucosa may lead to epistaxis on the affected side and damage to the infraorbital nerve may cause paraesthesia in its sensory distribution (Summary box 27.3).

Summary box 27.3

Fractures of the zygomatic complex

- Damage to the infraorbital nerve is common, causing numbness of the cheek

Blow-out fractures of the orbit

Direct blunt trauma to the globe of the eye may push it back within the orbit. The globe is a fairly robust structure and as it is thrust backwards, the weakest plate of bone, most commonly the orbital floor, fractures and the orbital contents herniate down into the maxillary antrum. This soft tissue herniation may trap the inferior oblique and inferior rectus muscles, leading to failure of the eye to rotate upwards. Enophthalmos and diplopia can follow, although initially both may be concealed by oedema. Paraesthesia in the distribution of the infraorbital nerve may be an important clue to the blow-out fracture.

There should be a high index of suspicion of any possible orbital blow-out fracture. A coronal CT is the investigation of choice, as significant delay in treatment may be associated with less success than early diagnosis and treatment (Figure 27.9) (Summary box 27.4).

Summary box 27.4

Blow-out fractures of the orbit

- Damage to the infraorbital nerve is common, causing numbness of the cheek
- Any fracture that involves the orbital floor (Le Fort II and zygomatic complex) has the potential for orbital content entrapment

Figure 27.9 Previously undiagnosed left orbital blow-out fracture, presenting three months after the initial injury. Enophthalmos and lowered pupillary level are evident.

Nasoethmoidal complex fractures

Fractures of the nasoethmoidal complex, as opposed to isolated nasal bone fractures, are usually comminuted fractures involving the nasal bones, maxilla, infraorbital rims and the frontal bones. Such injuries can cause significant deformity (Figure 27.10), and due to disruption of the medial canthal ligaments may cause traumatic telecanthus (widened intercanthal distance).

Fractures of the mandible

The condylar neck is the weakest part of the mandible and is the

Figure 27.10 Nasoethmoidal complex fracture, demonstrating gross nasal deformity and traumatic telecanthus.

most frequent site of fracture (Figure 27.11), while other fractures tend to occur through unerupted teeth (the impacted wisdom tooth) or where the roots are long (the canine tooth). The mandible may fracture directly at the point of the blow, or indirectly at a point of weakness distant from the original blow. The latter is characteristically seen in the so-called 'guardsman' fracture, where a blow to the chin point may cause a direct fracture of the symphysis or parasymphysis of the lower jaw. Indirect transmission of the kinetic energy causes a unilateral or bilateral fracture of the mandibular condyles. Blows from below may cause the mandible to be thrust upwards fracturing the alveolus and teeth as they strike the maxillary dentition (Summary box 27.5).

Summary box 27.5

Fractures of the mandible

- The condylar neck is the weakest point and the most common site of mandibular fracture
- Indirect transmission of energy may fracture the mandibular condyle(s)

Figure 27.11 The patterns of fracture of the mandible. (1) The neck of the condyle is the most common site, followed by (2) the angle of the mandible through the last tooth. (3) The third point of weakness is in the region of the canine tooth.

A 'guardsman' fracture is so called because it refers to the Queen's Guards who, when they fainted on parade, still held themselves in a position of attention. As a consequence, if they fell forward, the first point of contact with the ground would be the point of the chin. This resulted in a direct fracture of the symphysis/parasymphysis of the mandible, and indirect fractures of both mandibular condyles.

TREATMENT

Soft tissue injuries

Facial soft tissues have an excellent blood supply and heal well. They should be sutured as soon as possible following the injury after careful exploration, debridement and cleaning, particularly if foreign bodies are embedded in the wounds. Most lacerations can be closed using local anaesthesia. If the patient is due to have a general anaesthetic and there is a delay, then the wounds should be temporarily closed in advance, using local anaesthesia.

Great care should be taken to replace tissues accurately, particularly in cosmetically important landmarks, such as the vermillion border of the lips, the eyelids and nasal contours. Muscle and underlying tissues should be brought together with absorbable sutures so that the edges of the wound lie passively within 2 mm of their final position. Then, fine monofilament sutures (5-0 or 6-0) are used to bring the wound edges together (Figure 27.12). Sutures should be placed so as to avoid compromising the blood supply of the apices of small flaps. Broad spectrum antibiotics should be prescribed. Ideally, alternate sutures should be removed from the third day with the remaining sutures removed on the fifth day.

Intraoral lacerations should be closed with resorbable sutures. The depth of lacerations to mobile structures, such as the tongue and soft palate, can easily be underestimated. Failure to close the deeper layers of intraoral lacerations may lead to wound dehiscence. The subsequent scars will be thickened and uncomfortable to the patient (Summary box 27.6).

Summary box 27.6

Facial lacerations

- Wounds must be thoroughly cleaned of dirt and debris to avoid tattooing
- Replace tissues accurately, especially the vermillion border

Figure 27.12 Facial wound. The method of skin closure avoiding inversion of the wound edges. The skin suture has a greater bite of deep tissue than at the surface.

Skin loss

Substantial skin and deeper tissue loss can occur as a result of human bite injuries (Figure 27.13), most commonly the nose and ear. Small areas of tissue loss can be closed by careful undermining of the surrounding soft tissues, providing that there is no significant tension on the wound edges and no distortion of the

Figure 27.13 Skin and cartilage loss sustained as a result of human bite injuries. (a) Nose; (b) ear.

surrounding tissues or structures. Larger areas of skin loss require careful assessment and planned reconstruction with grafts and local tissue flaps.

Facial nerve injury

The branches of the facial nerve may be severed in the depths of a lateral facial wound. If this is suspected, primary repair should be attempted, particularly where clinical signs suggest that a major division is involved. Locating the divided branches in oedematous and damaged tissue can prove extremely difficult. Proximal and distal flaps in relatively normal adjacent tissue may have to be raised to identify the nerve on each side of the laceration. The severed nerve ends may then be approximated using an operating microscope. Attempt at primary repair should always be undertaken, as secondary repair is generally unsatisfactory (Summary box 27.7).

Summary box 27.7

Facial nerve injury

- Primary repair is the most appropriate treatment

Parotid duct

Lacerations in the same vicinity as those which transect the facial nerve may also transect the parotid duct. The suggested management is to insert a fine cannula into the parotid duct from within the mouth and pass it posteriorly until it appears in the wound. The position of the proximal duct should then be identified and this portion passed over the cannula, so approxi-

imating the severed portions of the duct. The two portions of the duct are then anastomosed, and the cannula left in position for several days in an attempt to prevent post-anastomotic stricture (Summary box 27.8).

Summary box 27.8

Parotid duct transection

- Cannulate from the mouth and anastomose over the stent

The lacrimal apparatus

The nasolacrimal apparatus may be involved in damage to the eyelids and skeletal facial injuries involving the naso-orbital region. The tissues are generally grossly oedematous and the manipulation required to reduce the fractures adds to the difficulty of identifying the canaliculae. Most surgeons do not attempt repair primarily, but refer to an ophthalmic surgeon if epiphora becomes a problem later, as many heal spontaneously.

Frontal bone fractures

The presence of depressed frontal bone fractures and fractures of the posterior wall of the frontal sinus require neurosurgical collaboration. However, fractures of the anterior wall of the sinus are amenable to maxillofacial techniques for reduction and fixation. Access may be through pre-existing lacerations overlying the area, but excellent access with minimal morbidity is achieved using the bicoronal scalp flap (see below). Bone fragments may then be reduced and fixed using titanium bone plates and screws. Any missing bone should be replaced with bone grafts, thereby avoiding any cosmetic forehead depression postoperatively.

Fractures of the maxilla

The principle of reducing and stabilising fractures of the frontal and facial bones is that the surgeon starts at the top and works down. Where no convenient lacerations exist, fractures of the frontal bone, supraorbital ridge and nasal root may be approached through a bicoronal incision, at the vault of the skull, high in the hair line. The incision is taken from just in front of each ear across the vault of the skull. The skin and galea are reflected forwards until the supraorbital ridges are exposed. The supraorbital nerves are identified and freed and the flap extended as required. The nasal bones, lateral orbital rim, frontal bones and zygomatic arches may all be exposed through this approach. The fractured bones may be reduced and fixed by stainless steel wire or titanium mini/microplates, under direct vision. Bone deficiencies in this area may be made up with free, outer cortical cranial bone grafts, with the donor sites available through the bicoronal incision. Where there has been disruption of the medial canthal ligaments, these should be identified and sutured/wired to the opposite side to restore canthal width.

When the stabilisation of the upper part of the face is complete, attention may be turned to the midface. Incisions in the lower eyelid (blepharoplasty incision), lower conjunctival sac or infraorbital region are used to explore fractures of the infra-orbital rim. These also give access to the orbital floor and are used to treat orbital blow-out fractures. The fractured rim may be fixed using mini/microplates or wires as above, and the floor of the orbit reconstructed with bone, titanium mesh or alloplastic material.

The lower part of the maxilla is approached through a gingival sulcus incision above the maxillary teeth as far back as the second molar. Fractures are fixed with plates or wires. The dental arch is restored to its original shape as far as possible so that it matches the premorbid occlusion with the mandibular arch. To achieve accurate location, dental arch bars, intermaxillary fixation screws or eyelet wires (see below) may need to be applied. Where this is anticipated, the necessary wiring is undertaken before the main part of the operation is commenced.

The principle of treatment is to restore the maxillary fragments to their original position. To achieve this, usually it is necessary to reduce the maxilla first with Rowe's disimpaction forceps, which grasp the palate between the nasal and palatal mucosa. Considerable force is sometimes required in a series of downward, forwards and sideways movements to mobilise it. After 2–3 weeks, full disimpaction is often impossible (Summary box 27.9).

Summary box 27.9

Fixation of maxillary fractures

- Orbital floor deficiencies may be made up with grafts, titanium mesh or alloplasts
- Intermaxillary fixation may be needed to achieve the correct occlusion

Fractures of the mandible

Fractures of the mandible were traditionally reduced indirectly and then fixed with intermaxillary fixation (IMF). IMF is simply a means of splinting the upper and lower arches of teeth together (Figure 27.14). However, the introduction of maxillofacial fixation systems utilising titanium fixtures has significantly altered the management of patients sustaining maxillofacial fractures. Prior to the introduction of these plating systems, patients would often have their jaws 'wired together' for a period of up to 6 weeks. Now, although patients may be placed in temporary IMF during their operative procedure, it is more often than not released at the end of the procedure when the rigid plate fixation has been applied (Figure 27.15).

Mandibular fractures may be explored through intraoral or extraoral incisions according to the access required. Pre-existing

Figure 27.14 Intermaxillary fixation using eyelet wires.

Figure 27.15 A fractured mandible treated by open reduction and fixation using a titanium miniplate. No postoperative intermaxillary fixation (IMF) has been used. (a) Posteroanterior view; (b) orthopantomogram.

lacerations overlying the mandible may be used to gain access to the fracture (Figure 27.16). To be sure of achieving a correct dental occlusion, it is wise to use temporary intraoperative IMF. There are occasions where, in spite of rigid fixation with titanium miniplates, IMF or elastic traction is still required in the postoperative period. In this event, the IMF is removed during the recovery from anaesthesia, so as not to risk complications involving the airway. The IMF may then be reapplied when the patient has fully recovered from the general anaesthetic.

Fractures of the edentulous (non-tooth-bearing) mandible are generally reduced and fixed using titanium plates. In the very atrophic mandible, the raising of the periosteum should be kept to a minimum as the blood supply to the jaw may be compromised (Summary box 27.10).

Summary box 27.10

Fixation of the mandible

- Plating has made long term jaw wiring almost redundant

Fractures of the mandibular condyle may cause disturbance of the occlusion with deviation of the mandible to the side of the fracture. In unilateral fractures, which are minimally displaced,

Figure 27.16 Comminuted fracture of the mandible approached through a pre-existing laceration.

this disturbance may not be evident. However, displaced unilateral fractures and bilateral condylar fractures often present with such a disturbance and, as such, constitute an indication for open reduction and fixation of the condylar fractures to prevent the formation of an abnormal occlusion. This malocclusion develops due to the vertical pull of the muscles of mastication shortening the ramus height. The posterior teeth contact first and the anterior teeth remain apart. Functionally and cosmetically, this is undesirable and is difficult to counteract by secondary procedures. It is not adequate to simply fix the mandible in IMF, except in the most minimally displaced malocclusions. Open reduction and fixation of the fractured mandibular condyle within 7–14 days of the original injury is indicated if a significant malocclusion is evident in a unilateral condylar fracture with displacement, or in a bilateral condylar fracture (Summary box 27.11).

Summary box 27.11

Fixation of mandibular condyles

- If displaced or bilateral, with significant occlusal disturbance, surgical intervention will be required
- Reduction and plating helps prevent anterior open bite

Fractures of the zygomatic complex

Displacement of zygomatic complex fractures is usually in a posterior direction, although it is important to assess the actual displacement by studying the occipitomental radiographs. Most fractures may be reduced by the Gillies temporal approach. This entails an incision in the hairline, superficial to the temporal fossa, about 15 mm long, at 45° to the vertical. It is deepened down to and through the temporalis fascia. A channel is prepared below the fascia and down under the body of the zygoma and arch. A Bristow or Rowe elevator is then inserted beneath

Sir Harold Delf Gillies, 1882–1960, plastic surgeon, St Bartholomew's Hospital, London, UK. Born in New Zealand, widely considered the 'father of plastic surgery', started his craft to better the lives of the victims of the First World War. Later, he became a pioneer in gender reassignment (sex change) surgery. When he was finally knighted in 1930 for his wartime work, William Arbutnot-Lane commented 'Better late than never!'. He excelled in most sports (cricket, rowing, golf) and despite a stiff elbow from a childhood injury was an accomplished painter.

the body of the zygoma or arch, according to the site of the fracture. Force is then applied in the opposite direction to the displacement of the fracture. After reduction, the position of the zygoma can be checked by palpating the bony prominences of the zygomatic arch, and the lateral and inferior orbital rims. As all fractures of the zygoma, other than those solely of the arch, involve the orbital floor, it is essential to apply a forced duction test to ensure no limitation of movement of the inferior oblique and inferior rectus muscles. For this to be done, the lower eyelid is retracted and the inferior rectus grabbed in the lower fornix. The globe can then be rotated upwards and should move freely. Any restriction in movement suggests entrapment of the infraorbital soft tissues, and the floor of the orbit should be explored as for a blow-out fracture (see below).

Should the fracture be unstable, open reduction and fixation of the fracture may be necessary. The frontozygomatic suture may be exposed by a small incision just behind the lateral part of the eyebrow and visualised. Displacements may be reduced and fixed with intraosseous wires or bone plates. Occasionally, it is necessary to explore and fix fractures at the infraorbital rim (see above under Fractures of the maxilla), or at the zygomatic buttress intraorally (Summary box 27.12).

Summary box 27.12

Fixation of fractures of the zygomatic complex

- The arch is elevated
- Ocular tethering should be checked if the fracture involves the orbital floor
- Regular postoperative observations must be made for retrobulbar haemorrhage

All patients who have had operations involving the orbit should have formal eye observations in the postoperative period. The condition of the eye, pupil size and light reaction should be recorded. Occasional complications occur, the most serious of which is a developing retrobulbar haematoma. Increasing proptosis and loss of vision constitute a postoperative emergency requiring immediate action to reduce the pressure of the haematoma.

Orbital blow-out fractures

These fractures are ideally treated within 10–14 days of the original injury. The aim of treatment is to reduce any soft tissue herniation of the periorbital (Figure 27.17), restore the continuity of the orbital floor, and restore any functional deficit of ocular function caused by extraocular muscle dysfunction. The floor of the orbit is approached either through a blepharoplasty incision in the lower eyelid or through the inferior fornix. The infraorbital margin is identified and the periosteum raised, attempting to avoid displacement of the delicate fragments of bone constituting the fracture. The periorbital soft tissues are gently separated from the bone of the fracture and freed so that no trapping or soft tissue herniation into the antrum remains. Defects of the orbital floor may be made up with bone grafts or from a variety of sources, such as titanium mesh or other suitably rigid materials. These materials may be fixed in place with wires, screws or plates (Summary box 27.13).

Walter Rowley Bristow, 1882–1947, orthopaedic surgeon, St Thomas's Hospital, London, UK.

Henri Luc, 1855–1925, otolaryngologist, in Paris, France, described his operation in 1889.

Walter Whitehead, 1840–1913, surgeon, The Royal Infirmary, Manchester, UK. Whitehead's varnish consists of iodoform, benzoin, storax and Tolu balsam in ether.

Figure 27.17 Coronal computed tomographic (CT) scan showing a left orbital blow-out fracture, with evident soft-tissue herniation into the maxillary antrum.

Summary box 27.13

Orbital blow-out fractures

- Defects of the orbital floor can be made up with bone graft or with synthetic materials

GENERAL

Fractures of the facial skeleton are almost always compound and prophylactic antibiotics are important. Penicillin/amoxycillin and metronidazole singly or in combination are ideal for those patients who are not allergic to them.

All patients with fractures of the facial skeleton benefit from intraoperative and postoperative dexamethasone, to reduce facial oedema (Summary box 27.14).

Summary box 27.14

General principles in facial fractures

- Prophylactic antibiotics should be given
- Dexamethasone may help to reduce facial oedema

LEARNING OBJECTIVES

To understand:

- That the management of trauma is based on physiology, as well as anatomy (as in general surgery)
- The gross and surgical anatomy of the chest and abdomen
- The pathophysiology of torso injury
- The strength and weaknesses of clinical assessment in the injured patient
- The use of special investigations and their limitations
- The operative approaches to the thoracic cavity
- The special features of an emergency department thoracotomy for haemorrhage control
- The indications for and techniques of the trauma laparotomy
- The philosophy of damage control surgery

INTRODUCTION

The torso is generally regarded as the area between the neck and the groin, made up of the thorax and abdomen. This is the largest area of the body and is commonly injured. Because injury does not respect anatomical boundaries, division of the body into abdomen and thorax is artificial, and injury to the torso, with its associated physiological consequences, is more appropriate. About 42 per cent of all deaths are the result of brain injury, but some 39 per cent of all trauma deaths are caused by major haemorrhage, usually from torso injury (Figure 28.1).

Although initially injury was treated on an anatomical basis, it has become clear that physiology should be the over-riding

consideration, and the driver of successful resuscitation is therefore the preservation of normal physiology. Techniques such as 'damage control resuscitation' and 'damage control surgery' have dramatically improved survival through an understanding of the best techniques required to restore physiological stability (see Chapters 24 and 32).

INJURY MECHANISMS ASSOCIATED WITH TORSO TRAUMA

Injury often traverses different anatomical zones of the body, affecting structures on both sides of traditional anatomical zones. These zones are known as 'junctional zones'.

Junctional zones

The key junctional zones are:

- between the neck and the thorax;
- between the thorax and the abdomen;
- between the abdomen, the pelvic structures and the groin.

These zones represent surgical challenges in terms of both the diagnosis of the area of injury and the surgical approach, which have to be balanced against the physiological stability of the patient.

Root of the neck

Most injuries affecting the base of the neck also affect the upper mediastinum and thoracic inlet. Choice of access is determined by the need for surgical control of the vascular structures contained within.

Figure 28.1 Causes of death in trauma. CNS, central nervous system; MOF, multiple organ failure.

The mediastinum

The zone overlying the mediastinum with its major vessels and the heart is also an extremely high-risk area for penetrating wounds. Any wound in this region should immediately raise the suspicion of an associated cardiac or major vascular injury even in the absence of initial gross physical signs.

Diaphragm

The thorax and abdomen are separated by the diaphragm, which is mainly responsible for breathing, and moves during breathing, between the fourth to the eighth interspace. Any penetrating injury of the lower half of the chest may therefore have penetrated the diaphragm and entered the abdomen. Injuries in this junctional zone, therefore, should be managed as if both cavities had been penetrated (Figure 28.2).

Pelvic structures and groin

The pelvis contains a large plexus of vessels, both venous and arterial. Should injury occur, control of haemorrhage can prove to be exceptionally difficult and may require control of both inflow and outflow. This may involve surgical control at the groin of the external iliac and femoral vessels, as well as at the aortic and cava level. Angioembolisation can be a very useful adjunct to treatment.

Retroperitoneum

Injury to the retroperitoneum is often difficult to diagnose, especially in the presence of other injury, when the signs may be masked. Intraperitoneal diagnostic tests (ultrasound and diagnostic peritoneal lavage) may be negative. The best diagnostic modality is the computed tomography (CT) scan, but this requires a physiologically stable patient. The retroperitoneum is divided into three zones (Figure 28.3):

- 1 Zone 1 (central): central haematomas should always be explored, once proximal and distal vascular control has been obtained.
- 2 Zone 2 (lateral): lateral haematomas are usually renal in origin and can be managed non-operatively, they may sometimes require angioembolisation.
- 3 Zone 3 (pelvic): pelvic haematomas are exceptionally difficult to control and, whenever possible, should not be opened; they should be controlled with packing (intra- or extraperitoneal) and angioembolisation (Summary box 28.1).

Figure 28.3 The zones of the retroperitoneum. Zone 1, central; zone 2, lateral; zone 3, pelvic.

Summary box 28.1

Junctional zones

- Neck
- Mediastinum
- Diaphragm
- Groin
- Retroperitoneum

CRITICAL PHYSIOLOGY

Resuscitation of all injuries to the chest and abdomen should follow traditional Advanced Trauma Life Support (ATLS) principles (Table 28.1 and see Chapter 24).

Bleeding is the major problem for diagnosis. This may be obvious at the time of evaluation; however, in the young fit individual, bleeding into the chest and abdomen may only produce subtle changes in vital measures and therefore be difficult to assess (Table 28.2). Bleeding occurs from five major sites: 'one on the floor and four more':

Figure 28.2 The extent of the abdomen.

- 1 external (i.e. skin);
- 2 chest;
- 3 abdomen;
- 4 pelvis;
- 5 extremities (e.g. fractures).

Although obvious injury may be present, traditional indicators (such as pulse rate) are unreliable in young patients. A normal pulse for a middle-aged patient may be a significantly raised pulse for a young fit person.

Table 28.1 Advanced Trauma Life Support (ATLS) principles of resuscitation.

A	Airway
B	Breathing
C	Circulation
D	Disability (neurology)
E	Environment and exposure

Table 28.2 Clinical indicators of potential ongoing bleeding in torso trauma.

Physiological	Increasing respiratory rate Increasing pulse rate Falling blood pressure Rising serum lactate
Anatomical	Visible bleeding Injury in close proximity to major vessels Penetrating injury with a retained missile

THORACIC INJURY

Thoracic injury accounts for 25 per cent of all severe injuries. In a further 25 per cent, it may be a significant contributor to the subsequent death of the patient. In most of these patients, the cause of death is haemorrhage.

Chest injuries are often life-threatening, either in their own right or in conjunction with other system injuries. About 80 per cent of patients with chest injury can be managed non-operatively. The key to a good outcome is early physiological resuscitation followed by a correct diagnosis.

Investigation

Routine investigation in the emergency department of injury to the chest is based on clinical examination, supplemented by chest radiography. Ultrasound can be used to differentiate between contusion and the actual presence of blood. A chest tube can be a diagnostic procedure, as well as a therapeutic one, and the benefits of insertion often outweigh the risks.

The pitfalls of investigation are:

- failure to auscultate both front and back (an inflated lung will 'float' on a haemothorax, so auscultation from the front may sound normal);
- failure to pass a nasogastric tube if rupture of the diaphragm is suspected;
- pursuing radiological investigation (radiography or CT scan) instead of resuscitation in the unstable patient.

Computed tomography scan

The CT scan has become the principal and most reliable examination for major injury in thoracic trauma. Scanning with contrast allows for three-dimensional reconstruction of the chest and abdomen, as well as of the bony skeleton. In blunt chest trauma, the CT scan will allow the definition of fractures, as well as showing haematomas, pneumothoraces and pulmonary contusion. In penetrating trauma, the scan may show the track or presence of the missile and allow the proper planning of definitive surgery.

CT scanning has replaced angiography as the diagnostic modality of choice for the assessment of the thoracic aorta (Summary box 28.2).

Summary box 28.2

Investigation of chest injuries

- Directly or indirectly involved in 50 per cent of trauma deaths in the United States.
- Eighty per cent can be managed non-operatively
- A chest radiograph is the investigation of first choice
- A spiral computed tomography scan provides rapid diagnoses in the chest and abdomen
- A chest drain can be diagnostic as well as therapeutic

Management

Most patients who have suffered penetrating injury to the chest can be managed with appropriate resuscitation and drainage of haematoma.

If a sucking chest wound is present, this should not be fully closed but should be covered with a piece of plastic, closed on three sides, to form a one-way valve, and thereafter an underwater chest drain should be inserted remote from the wound. No attempt should be made to close a sucking chest wound until controlled drainage has been achieved, in case a stable open pneumothorax is converted into an unstable tension pneumothorax.

In blunt injury, most bleeding occurs from the intercostal or internal mammary vessels and it is relatively rare for these to require surgery. If bleeding does not stop spontaneously, the vessels can be tied off or encircled. In blunt chest compressive injury, there is injury to the ribs and frequently to the underlying structures as well, with an associated lung contusion (Summary box 28.3).

Summary box 28.3

Closed management of chest injuries

- About 80 per cent of chest injuries can be managed closed
- If there is an open wound, insert a chest drain
- Do not close a sucking chest wound until a drain is in place
- If bleeding persists, the chest will need to be opened

The patient *in extremis* with exsanguinating chest haemorrhage will be discussed in the section below under Emergency thoracotomy.

Life-threatening injuries can be remembered as the 'deadly dozen'. Six are immediately life-threatening and should be

sought during the primary survey and six are potentially life-threatening and should be detected during the secondary survey (Table 28.3).

Table 28.3 The 'deadly dozen' threats to life from chest injury.

Immediately life threatening	Airway obstruction
	Tension pneumothorax
	Pericardial tamponade
	Open pneumothorax
	Massive haemothorax
	Flail chest
Potentially life threatening	Aortic injuries
	Tracheobronchial injuries
	Myocardial contusion
	Rupture of diaphragm
	Oesophageal injuries
	Pulmonary contusion

Efficient initial assessment should focus on identifying and correcting the immediate threats to life. A high index of suspicion must be maintained thereafter to diagnose the potential threats to life as their symptoms and signs can be very subtle. Early consultation and referral to a trauma centre is advised in cases of doubt.

Immediate life-threatening injuries

Airway obstruction

Early intubation is very important, particularly in cases of neck haematoma or possible airway oedema. Airway distortion can be insidious and progressive and can make delayed intubation more difficult if not impossible.

Tension pneumothorax

A tension pneumothorax develops when a 'one-way valve' air leak occurs either from the lung or through the chest wall. Air is sucked into the thoracic cavity without any means of escape, completely collapsing then compressing the affected lung. The mediastinum is displaced to the opposite side, decreasing venous return and compressing the opposite lung.

The most common causes are penetrating chest trauma, blunt chest trauma with parenchymal lung injury and air leak that did not spontaneously close, iatrogenic lung punctures (e.g. due to subclavian central venepuncture) and mechanical positive pressure ventilation.

The clinical presentation is dramatic. The patient is increasingly panicky with tachypnoea, dyspnoea and distended neck veins (similar to pericardial tamponade). Clinical examination may reveal tracheal deviation. This is a late finding and is not necessary to clinically confirm diagnosis. There will also be hyper-resonance and absent breath sounds over the affected hemithorax. Tension pneumothorax is a clinical diagnosis and treatment should never be delayed by waiting for radiological confirmation (Figure 28.4).

Treatment consists of immediate decompression, initially by rapid insertion of a large-bore needle into the second intercostal space in the midclavicular line of the affected hemithorax, and

Figure 28.4 Radiological appearance of a tension pneumothorax.

then followed by insertion of a chest tube through the fifth intercostal space in the anterior axillary line.

Pericardial tamponade

Pericardial tamponade needs to be differentiated from a tension pneumothorax in the shocked patient with distended neck veins. It is most commonly the result of penetrating trauma. Accumulation of a relatively small amount of blood into the non-distensible pericardial sac can produce physiological obstruction of the heart. All patients with penetrating injury anywhere near the heart plus shock must be considered to have a cardiac injury until proven otherwise. Classically, the presentation consists of venous pressure elevation, decline in arterial pressure with tachycardia, and muffled heart sounds. A high index of suspicion and further diagnostic investigations will be needed to make the diagnosis in those cases which are not clinically obvious. This includes chest radiography looking for an enlarged heart shadow or a cardiac ultrasound showing fluid in the pericardial sac. A central line should be inserted checking for a rising central venous pressure. However, in cases in which major bleeding from other sites has taken place, the neck veins may be flat.

Needle pericardiocentesis may allow the aspiration of a few millilitres of blood and this, along with rapid volume resuscitation to increase preload, can buy enough time to move the patient to the operating room. However, in penetrating injury to the heart, there is usually a substantial clot in the pericardium, which may prevent aspiration. A dry pericardiocentesis proves only that there is a 'clot' on both ends of the needle! Pericardiocentesis has a high potential for iatrogenic injury to the heart and it should at the most be regarded as a desperate temporising measure in a transport situation (under electrocardiogram (ECG) control). The correct immediate treatment of tamponade is operative (sternotomy or left thoracotomy), with repair of the heart in the operating theatre if time allows or otherwise in the emergency room (Summary box 28.4).

Summary box 28.4**Pericardial tamponade**

- The presentation is similar to a tension pneumothorax: deteriorating cyanosis tachycardia and agitation
- Ultrasound is diagnostic
- The central venous pressure may not be elevated if the circulating volume is depleted, e.g. because of other injuries
- Pericardiocentesis is a temporising measure only with a high complication rate and is not a substitute for immediate operative intervention

Open pneumothorax ('sucking chest wound')

This is due to a large open defect in the chest (>3 cm), leading to equilibration between intrathoracic and atmospheric pressure. Air accumulates in the hemithorax (rather than in the lung) with each inspiration, leading to profound hypoventilation on the affected side and hypoxia. Signs and symptoms are usually proportionate to the size of the defect. If there is a valvular effect, increasing amounts of air in the pleura will result in a tension pneumothorax (see above under Tension pneumothorax).

Initial management consists of promptly closing the defect with a sterile occlusive plastic dressing (e.g. Opsite®), taped on three sides to act as a flutter-type valve. A chest tube is inserted as soon as possible in a site remote from the injury site. Definitive treatment may warrant formal debridement and closure, and early referral.

The following points are important in the management of an open pneumothorax:

- a common problem is using too small a tube: a 28FG or larger tube should be used in an adult;
- If the lung does not reinflate, the drain should be placed on low-pressure (5 cm water) suction;
- a second drain is sometimes necessary (but see below under Tracheobronchial injuries);
- physiotherapy and active mobilisation should begin as soon as possible.

Massive haemothorax

The most common cause of massive haemothorax in blunt injury is continuing bleeding from torn intercostal vessels or occasionally from the internal mammary artery.

Accumulation of blood in a hemithorax can significantly compromise respiratory efforts, compressing the lung and preventing adequate ventilation. Presentation is with haemorrhagic shock, flat neck veins, unilateral absence of breath sounds and dullness to percussion. The treatment consists of correcting the hypovolaemic shock, insertion of an intercostal drain and, in some cases, intubation.

Blood in the pleural space should be removed as completely and rapidly as possible to prevent ongoing bleeding, empyema or a late fibrothorax. Clamping a chest drain to tamponade a massive haemothorax is usually not helpful.

Initial drainage of more than 1500 mL of blood or ongoing haemorrhage of more than 200 mL/hour over 3–4 hours is generally considered an indication for urgent thoracotomy.

Flail chest

This condition usually results from blunt trauma associated

with multiple rib fractures, and is defined as three or more ribs fractured in two or more places. The blunt force required to disrupt the integrity of the thoracic cage typically produces an underlying pulmonary contusion as well. The diagnosis is made clinically, not by radiography. On inspiration, the loose segment of the chest wall is displaced inwards and therefore less air moves into the lungs. To confirm the diagnosis, the chest wall can be observed for paradoxical motion of a chest wall segment during respiration and during coughing. Voluntary splinting of the chest wall occurs as a result of pain, so mechanically impaired chest wall movement and the associated lung contusion all contribute to the hypoxia. There is a high risk of developing a pneumothorax or haemothorax.

Traditionally, mechanical ventilation was used to 'internally splint' the chest, but had a price in terms of intensive care unit resources and ventilation-dependent morbidity. Currently, treatment consists of oxygen administration, adequate analgesia (including opiates) and physiotherapy. If a chest tube is *in situ*, intrapleural local analgesia can be used as well. Ventilation is reserved for cases developing respiratory failure despite adequate analgesia and oxygen. Surgery to stabilise the flail chest may be useful in a selected group of patients with isolated or severe chest injury and pulmonary contusion.

Potentially life-threatening injuries**Thoracic aortic disruption**

Traumatic aortic rupture is a common cause of sudden death after an automobile collision or fall from a great height. The vessel is relatively fixed distal to the ligamentum arteriosum, just distal to the origin of the left subclavian artery. The shear forces from a sudden impact disrupt the intima and media. If the adventitia is intact, the patient may remain stable. For the subgroup of immediate survivors, salvage is frequently possible if aortic rupture is identified and treated early. It should be clinically suspected in patients with asymmetry of upper or upper and lower extremity blood pressure, widened pulse pressure and chest wall contusion. Erect chest radiography can also suggest thoracic aortic disruption, the most common radiological finding being a widened mediastinum (Figure 28.5). The diagnosis is confirmed by a CT scan of the mediastinum (Figure 28.6) or possibly by transoesophageal echocardiography.

Initially, management consists of control of the systolic arterial blood pressure (to less than 100 mmHg). Thereafter, an endovascular intra-aortic stent (Figure 28.7) can be placed or the tear can be operatively repaired by direct repair or excision and grafting using a Dacron graft.

Tracheobronchial injuries

Severe subcutaneous emphysema with respiratory compromise can suggest tracheobronchial disruption. A chest drain placed on the affected side will reveal a large air leak and the collapsed lung may fail to re-expand. If after insertion of a second drain the lung fails to re-expand, referral to a trauma centre is advised.

Bronchoscopy is diagnostic. Treatment involves intubation of the unaffected bronchus followed by operative repair.

Blunt myocardial injury

Significant blunt cardiac injury that causes haemodynamic instability is rare. Blunt myocardial injury should be suspected in any patient sustaining blunt trauma who develops early ECG abnormalities.

Figure 28.5 Chest radiograph showing a widened mediastinum.

Figure 28.6 Computed tomography scan showing aortic disruption.

Two-dimensional echocardiography may show wall motion abnormalities. A transoesophageal echocardiogram may also be helpful. There is very little evidence that enzyme estimations have any place in diagnosis.

All patients with myocardial contusion diagnosed by conduction abnormalities are at risk of developing sudden dysrhythmias and should be closely monitored.

Diaphragmatic injuries

Any penetrating injury below the fifth intercostal space should raise suspicion of diaphragmatic penetration and, therefore, injury to the abdominal contents.

Blunt injury to the diaphragm is usually caused by a compressive force applied to the pelvis and abdomen. The diaphragmatic rupture is usually large, with herniation of the abdominal contents into the chest. Diagnosis of blunt diaphragmatic rupture is missed even more often than penetrating injuries in the acute phase.

Most diaphragmatic injuries are silent and the presenting features are those of injury to the surrounding organs. There is no single standard investigation. Chest radiography after placement of a nasogastric tube may be helpful (as this may show the stomach herniated into the chest). Contrast studies of the upper or lower gastrointestinal tract, CT scan and diagnostic peritoneal

Figure 28.7 Aortic tear showing presence of stent.

lavage all lack positive or negative predictive value. The most accurate evaluation is by video-assisted thoracoscopy (VATS) or laparoscopy, the latter offering the advantage of allowing the surgeon to proceed to a repair and additional evaluation of the abdominal organs (Summary box 28.5).

Summary box 28.5

Blunt injuries

- Rupture of the diaphragm is easily missed
- Myocardial injury must be suspected if there are abnormal ECG changes
- Mortality rises rapidly with delay in diagnosis of oesophageal rupture
- In severe pulmonary contusion ventilation may be needed

Operative repair is recommended in all cases. All penetrating diaphragmatic injury must be repaired via the abdomen and not the chest, to rule out penetrating hollow viscus injury.

The thorax is at negative pressure and the abdomen is at positive pressure. A late complication of rupture of the diaphragm is herniation of the abdominal contents into the chest. Strangulation of any of the contents can then occur, and the patients have a high mortality rate.

Oesophageal injury

Most oesophageal injuries result from penetrating trauma; blunt injury is rare. A high index of suspicion is required. The patient can present with odynophagia (pain on swallowing foods or fluids), subcutaneous or mediastinal emphysema, pleural effusion, air in the retro-oesophageal space and unexplained fever. Mediastinal and deep cervical emphysema are evidence of an aerodigestive injury until proven otherwise.

The mortality rate rises exponentially if treatment is delayed. A combination of oesophagogram in the decubitus position and oesophagoscopy confirm the diagnosis in the great majority of cases. The treatment is operative repair and drainage.

Pulmonary contusion

Pulmonary contusion occurs following blunt trauma, usually

underneath a flail segment or fractured ribs. This is a very common, potentially lethal injury and the major cause of hypoxaemia after blunt trauma.

The natural progression of pulmonary contusion is worsening hypoxemia for the first 24–48 hours. The chest radiography findings are typically delayed. Contrast CT scanning can be confirmatory. Haemoptysis or blood in the endotracheal tube is a sign of pulmonary contusion.

In mild contusion, the treatment is oxygen administration, aggressive pulmonary toilet and adequate analgesia. In more severe cases, mechanical ventilation is necessary. Normovolaemia is critical for adequate tissue perfusion and fluid restriction is not advised.

Continuing blood loss

The first principle of all care is to assess and treat the patient according to the physiology. Initial blood loss of more than 1500 mL indicates the potential for class III shock, and any ongoing bleeding must be dealt with surgically, as soon as possible. Similarly, an ongoing blood loss of more than 200 mL/hour for 3 consecutive hours requires resuscitative surgery to stop the bleeding.

EMERGENCY THORACOTOMY

Emergency thoracic surgery is an essential part of the armamentarium of any surgeon dealing with major trauma. A timely thoracotomy for the correct indications can be the key step in saving an injured patient's life.

Indications for thoracotomy include the need to perform:

- internal cardiac massage;
- control of haemorrhage from injury to the heart or lung;
- control of intrathoracic haemorrhage from other causes;
- control of massive air leak.

The clinical decision as to whether a casualty requires an emergency department thoracotomy (EDT) or can be transferred to the operating theatre can be complex. It is far better to perform a thoracotomy in the operating theatre, either through an antero-lateral approach or a median sternotomy, with good light and assistance, and the potential for autotransfusion or bypass, than it is to attempt heroic emergency surgery in the resuscitation area. However, if the patient is *in extremis* with a falling systolic blood pressure, there is no choice but to proceed immediately with a left anterolateral thoracotomy. In certain circumstances, when care is futile, it may not need to be performed at all. A resuscitation room thoracotomy following blunt trauma has limited indications and is rarely successful.

Emergency department thoracotomy

EDT should be reserved for those patients suffering penetrating injury in whom signs of life are still present. Patients who have received cardiopulmonary resuscitation (CPR) in the pre-hospital phase of their care are unlikely to survive, and electrical activity must be present. The survival rates for EDT in patients with penetrating trauma in whom the blood pressure is falling despite adequate resuscitation are shown in Table 28.4.

It is important to make a distinction between:

- immediate thoracotomy in the emergency department for the control of haemorrhage, cardiac tamponade, or for internal cardiac massage;

Table 28.4 Survival rates for thoracotomy in patients with penetrating trauma.

Blood pressure despite resuscitation	Survival (%)
>60 mmHg	60
>40 mmHg	30
<40 mmHg	3

- planned thoracotomy for definitive correction of the problem: this usually takes place in the more controlled environment of the operating theatre.
In certain situations, EDT is considered futile:
- CPR in the absence of endotracheal intubation for more than 5 minutes;
- CPR for more than 10 minutes (with or without endotracheal intubation);
- blunt trauma when there have been no signs of life at scene (see above).

Planned emergency thoracotomy

Planned emergency thoracotomy implies an emergency thoracotomy performed as a planned procedure in the operating room, directed at the management of a specific injury. As such, the approach chosen is dependent on the indication for surgery and the organ injured (Table 28.5). Some organs are best approached through a median sternotomy.

Otherwise, the thoracotomy may be right- or left-sided, and these may be joined, producing the so-called ‘clamshell incision’. This gives excellent exposure for any surgeon who is not routinely entering the chest.

Posterolateral thoracotomy is not generally used in the emergency situation because of the difficulties in positioning the patient.

Table 28.5 Different approaches to the contents of the chest cavity.

Approach	Best for
Left anterolateral thoracotomy	Left lung and lung hilum
	Thoracic aorta
	Origin of left subclavian artery
	Left side of heart
	Lower oesophagus
Right anterolateral thoracotomy	Right lung and lung hilum
	Azygos veins
	Superior vena cava
	Infradiaphragmatic inferior vena cava
	Upper oesophagus
	Thoracic trachea
Median sternotomy	Anterior aspect of heart
	Anterior mediastinum
	Ascending aorta and arch of aorta
	Pulmonary arteries
	Carina of the trachea

ABDOMINAL INJURY

Patients who have suffered abdominal trauma can generally be classified into the following categories based on their physiological condition after initial resuscitation:

- Haemodynamically ‘normal’: investigation can be completed before treatment is planned.
- Haemodynamically ‘stable’: investigation is more limited. It is aimed at establishing whether the patient can be managed non-operatively, whether angioembolisation can be used, or whether surgery is required.
- Haemodynamically ‘unstable’: investigations need to be suspended as immediate surgical correction of the bleeding is required.

A trauma laparotomy is the final step in the pathway to delineate intra-abdominal injury. Occasionally, it is difficult to determine the source of bleeding in the shocked multiply-injured patient. If doubt still exists, especially in the presence of other injuries, a laparotomy may still be the safest option.

Investigation

Investigations are driven by the cardiovascular status of the patient. In torso trauma, the best and most sensitive modality is a CT scan with intravenous contrast; however, in the unstable patient, this is generally not possible.

In patients with penetrating injury, metal markers (e.g. bent paper clips) should be placed on all external wounds before plain films are taken, irrespective of the area being radiographed, as this allows an assessment of the trajectory and helps to correlate the number of holes and the number of missiles which can be seen within the patient. This will help determine whether two holes are indicative of one missile passing through the patient, or two missiles, both retained internally (Figure 28.8).

The patient’s physiology must be assessed at regular intervals and, if there is an indication that the patient is still actively bleeding, then the source must be found. Blood loss into the abdomen can be subtle and there may be no clear clinical signs.

Figure 28.8 Abdominal radiograph of a gunshot wound showing bullet markers.

Blood is not an irritant and does not initially cause any abdominal pain. Distension is subjective, and a drop in the blood pressure may be a very late sign in a young fit patient. Examination in unstable patients should take place either in the emergency department or in the operating theatre if the patient is deteriorating rapidly.

Focused abdominal sonar for trauma

Focused abdominal sonar for trauma (FAST) is a technique whereby ultrasound (sonar) imaging is used to assess the torso for the presence of free blood, either in the abdominal cavity or in the pericardium. The technique therefore focuses on six areas: the pericardium, the areas around the liver and the spleen, the left and right pericolic gutters, and the peritoneal space in the pelvis. There should be no attempt to determine the nature or extent of the specific injury. FAST is usually a rapid, reproducible, portable and non-invasive bedside test, and can be performed at the same time as resuscitation. FAST is accurate at detecting >100 mL of free blood; however, it is very operator- and experience-dependent and, especially if the patient is very obese or the bowel is full of gas, it may be unreliable. Hollow viscus injury is difficult to diagnose, even in experienced hands, and has a low sensitivity (29–35 per cent) for organ injury without haemoperitoneum. FAST is also unreliable for excluding injury in penetrating trauma. If there is doubt, the FAST examination should be repeated (Summary box 28.6).

Summary box 28.6

Focused abdominal sonar for trauma

- It detects free fluid in the abdomen or pericardium
- It will not reliably detect less than 100 mL of free blood
- It does not identify injury to hollow viscus
- It cannot reliably exclude injury in penetrating trauma
- It may need repeating or supplementing with other investigations

Extensions of the FAST technique to include assessment of the chest for haemothorax and pneumothorax, as well as assessment of the extremities, depend on the experience of the operator and are not yet widely accepted.

Diagnostic peritoneal lavage

Diagnostic peritoneal lavage (DPL) is a test used to assess the presence of blood in the abdomen. A gastric tube is placed to empty the stomach and a urinary catheter is inserted to drain the bladder.

A cannula is inserted below the umbilicus, directed caudally and posteriorly. The cannula is aspirated for blood (>10 mL is deemed as positive) and, following this, 1000 mL of warmed Ringer's lactate solution is allowed to run into the abdomen and is then drained out. The presence of >100 000 red cells/ μ L or >500 white cells/ μ L is deemed positive (this is equivalent to 20 mL of free blood in the abdominal cavity). In the absence of laboratory facilities, a urine dipstick may be useful. Drainage of lavage fluid via a chest drain indicates penetration of the diaphragm.

Although DPL has largely been replaced by FAST (see above under Focused abdominal sonar for trauma), it remains the standard in many institutions where FAST is not available or is

unreliable. DPL is especially useful in the hypotensive, unstable patient with multiple injuries as a means of excluding intra-abdominal bleeding.

Computed tomography

CT has become the 'gold standard' for the intra-abdominal diagnosis of injury in the stable patient. The scan should be performed using intravenous contrast. CT is sensitive for blood, and individual organ injury, as well as for retroperitoneal injury. An entirely normal abdominal CT is usually sufficient to exclude injury.

The following points are important when performing CT:

- Despite its tremendous value, it remains an inappropriate investigation for unstable patients.
- If duodenal injury is suspected from the mechanism of injury, oral contrast may be helpful.
- If rectal and distal colonic injury is suspected in the absence of blood on rectal examination, rectal contrast may be helpful.

Diagnostic laparoscopy

Diagnostic laparoscopy (DL) or thoracoscopy may be a valuable screening investigation in stable patients with penetrating trauma, to detect or exclude peritoneal penetration and/or diaphragmatic injury.

In most institutions, evidence of penetration requires a laparotomy to evaluate organ injury, as it is difficult to exclude all intra-abdominal injuries laparoscopically. When used in this role DL reduces the non-therapeutic laparotomy rate. DL is not a substitute for open laparotomy, especially in the presence of haemoperitoneum or contamination.

INDIVIDUAL ORGAN INJURY

Liver

Blunt liver trauma occurs as a result of direct injury. The liver is a solid organ and compressive forces can easily burst the liver substance. The liver is usually compressed between the impacting object and the rib cage or vertebral column. Most injuries are relatively minor and can be managed non-operatively. Many are not even suspected at the time.

Penetrating trauma to the liver is relatively common. Bullets have a shock wave and when they pass through a solid structure, such as the liver, they cause significant damage some distance from the actual track of the bullet. Not all penetrating wounds require operative management and a number may stop bleeding spontaneously.

In the stable patient, CT is the investigation of choice. It provides information on the liver injury itself, as well as on injuries to the adjoining major vascular and biliary structures. Close proximity injury and injury in which there is a suggestion of a vascular component should be reimaged, as there is a significant risk of the development of subsequent ischaemia.

Liver injury can be graded and managed using the American Association for the Surgery of Trauma (AAST) Organ Injury Scale (OIS) (www.aast.org/injury).

Management

The operative management of liver injuries can be summarised as 'the four Ps':

- 1 push;

- 2 Pringle;
- 3 plug;
- 4 pack.

At laparotomy, the liver is reconstituted as best as possible in its normal position and bleeding is controlled by direct compression (push). The inflow from the portal triad is controlled by a Pringle's manoeuvre, with direct compression of the portal triad, either digitally or using a soft clamp (Figure 28.9). This has the effect of reducing arterial and portal venous inflow into the liver, although it does not control the backflow from the inferior vena cava and hepatic veins. Any holes due to penetrating injury can be plugged directly and, after controlling any arterial bleeding, the liver can then be packed (see below under Damage control surgery).

Bleeding points should be controlled locally when possible and such patients should subsequently undergo angioembolisation. It is not usually necessary to suture penetrating injuries of the liver. If there has been direct damage to the hepatic artery, it can be tied off. Damage to the portal vein must be repaired, as tying off the portal vein carries a greater than 50 per cent mortality rate. If it is not technically feasible to repair the vein at the time of surgery, it should be shunted and the patient referred to a specialist centre. A closed suction drainage system must be left *in situ* following hepatic surgery.

Penetrating injuries and deep tracts can be plugged using silicone tubing or a Sengstaken–Blakemore tube.

Finally, the liver can be definitively packed, restoring the anatomy as closely as possible. Placing omentum into cracks in the liver is not recommended (Summary box 28.7).

Biliary injuries

Isolated traumatic biliary injuries are rare, occur mainly from penetrating trauma, and often occur in association with injuries to other structures that lie in close proximity. The common bile duct can be repaired over a T-tube or drained and referred to appropriate care as part of damage control.

Figure 28.9 The Pringle manoeuvre.

Summary box 28.7

Liver trauma

- Blunt trauma occurs as the result of direct compression
- Penetrating trauma of the upper abdomen or lower thorax can damage the liver
- Computed tomography scanning is the investigation of choice, but only in the stable patient
- Surgical management consists of push, Pringle, plug and pack
- The hepatic artery can be tied off, but not the portal vein (stent)
- Closed suction should always be used

Spleen

Splenic injury occurs from direct blunt trauma. Most isolated splenic injuries, especially in children, can be managed non-operatively. However, in adults, especially in the presence of other injury, age >55 years, or physiological instability, splenectomy should be considered. The spleen can be packed, repaired or placed in a mesh bag. Splenectomy may be a safer option, especially in the unstable patient with multiple potential sites of bleeding and who is >55 years of age, due to risk of rebleed. In certain situations, selective angioembolisation of the spleen can play a role.

Following splenectomy, there are significant though transient changes to blood physiology. The platelet and white count rises and may mimic sepsis.

Pancreas

Most pancreatic injury occurs as a result of blunt trauma. The major problem is that of diagnosis, because the pancreas is a retroperitoneal organ. CT remains the mainstay of accurate diagnosis. Amylase estimation is only relatively sensitive.

Classically, the pancreas should be treated with conservative surgery and closed suction drainage. Injuries are treated according to the OIS system of the AAST. Injuries to the tail are treated by closed suction drainage, with distal pancreatectomy if the duct is involved. Proximal injuries (to the right of the superior mesenteric artery) are treated as conservatively as possible, although partial pancreatectomy may be necessary. The pylorus can be temporarily closed (pyloric exclusion) in association with a gastric drainage procedure. A Whipple's procedure (pancreaticoduodenectomy) is rarely needed and should not be performed in the emergency situation because of the very high associated mortality rate. A damage control procedure with packing and drainage should be performed and the patient referred for definitive surgery once stabilised.

Stomach

Most stomach injuries are caused by penetrating trauma. Blood may be present and is diagnostic if found in the nasogastric tube.

Surgical repair is required but great care must be taken to examine the stomach fully, as an injury to the front of the stomach can be expected to have an 'exit' wound elsewhere on the organ.

Duodenum

Duodenal injury is frequently associated with injuries to the

James Hogarth Pringle, 1863–1941, Australian-born surgeon, Royal Infirmary, Glasgow, UK.

Robert William Sengstaken, born 1923, surgeon, Garden City, NY, USA.

Allen Oldfather Whipple, 1881–1963, Valentine Mott Professor of Surgery, The College of Physicians and Surgeons, Columbia University, New York, NY, USA.

adjoining pancreas. Like the pancreas, the duodenum lies retroperitoneally and so injuries are hidden and only discovered late or at laparotomy performed for other reasons. The only sign may be gas in the periduodenal tissue seen at CT.

Smaller injuries can be repaired primarily. Major injuries and those also involving the head of the pancreas should undergo initial damage control surgery and be referred for definitive care.

Small bowel

The small bowel is frequently injured as a result of blunt trauma. The individual loops may be trapped, causing high-pressure rupture of a loop or tearing of the mesentery.

Small bowel injuries need urgent repair. Haemorrhage control takes priority and these wounds can be temporarily controlled with simple sutures. The small bowel can also be temporarily occluded until haemorrhage control has been achieved. In blunt trauma, the mesenteric vessels damage, and the bowel ischaemia which results, may dictate the extent of a resection. Resections should be carefully planned to limit the loss of viable small bowel but should be weighed against an excessive number of repairs or anastomoses. Haematomas in the small bowel mesenteric border need to be explored to rule out perforation. With low-energy wounds, primary repair can be performed after debridement of any dead tissue, whereas more destructive wounds associated with military-type weapons require resection and anastomosis.

Colon

Injuries to the colon from blunt injury are relatively infrequent, and are a more frequent penetrating injury. If relatively little contamination is present and the viability is satisfactory, such wounds can be repaired primarily. If, however, there is extensive contamination, the patient is physiologically unstable, or the bowel is of doubtful viability, then the colon can be closed off and a defunctioning colostomy formed.

Rectum

Only 5 per cent of colon injuries involve the rectum. These are generally from a penetrating injury, although occasionally the rectum may be damaged following fracture of the pelvis. Digital rectal examination will reveal the presence of blood, which is evidence of colorectal injury. These injuries are often associated with bladder and proximal urethral injury.

With intraperitoneal injuries, the rectum is managed as for colonic injuries. Full-thickness extraperitoneal rectal injuries should be managed with either a diverting end-colostomy and closure of the distal end (Hartmann's procedure) or a loop colostomy. Presacral drainage is generally no longer used.

Renal and urological tract injury

In the stable patient, CT scanning with contrast is the investigation of choice.

For assessment of bladder injury, a cystogram should be performed. A minimum of 400 mL of contrast is instilled into the bladder via a urethral catheter. The large volume is essential because a small volume may not produce a leak from a small bladder injury once the cystic muscle has contracted. It is important to assess the films as follows:

- with two views: anteroposterior and lateral;
- on two occasions: full and post-micturition.

Generally, renal injury is managed non-operatively unless the patient is unstable. The kidney can be angioembolised if required.

Ureteric injury is rare and is generally due to penetrating injury. Most ureters can be repaired or diverted if necessary.

Intraperitoneal ruptures of the bladder, usually from direct blunt injury, will require surgical repair. Extraperitoneal ruptures are usually associated with a fracture of the pelvis and will heal with adequate urine drainage (Summary box 28.8).

Summary box 28.8

Injuries to structures in the abdomen

- In children, splenic injury can be managed non-operatively
- Duodenal injuries are associated with pancreatic damage
- Small bowel injuries need urgent repair
- Large bowel injuries can be resected and stapled off
- Rectal injuries may be best managed initially with a defunctioning colostomy
- Kidney and urinary tract damage is best diagnosed with enhanced computed tomography scanning
- Intra-abdominal bladder tears need formal repair and drainage

ABDOMINAL COMPARTMENT SYNDROME AND THE OPEN ABDOMEN

Raised intra-abdominal pressure has far-reaching consequences for the patient; the syndrome that results is known as abdominal compartment syndrome (ACS). ACS is a major cause of morbidity and mortality in the critically ill patient and its early recognition is essential (Table 28.6).

In all cases of abdominal trauma in which the development of ACS in the immediate postoperative phase is considered a risk, the abdomen should be left open and managed as for damage control surgery.

DAMAGE CONTROL

Following major injury, protracted surgery in the physiologically unstable patient can in itself prove fatal. Patients with the 'deadly triad' of hypothermia, acidosis and coagulopathy are those at highest risk. 'Damage control' or 'damage limitation surgery' is a concept that originated from naval strategy, whereby a ship which has been damaged may have minimal repairs needed to prevent it from sinking, while definitive repairs wait until it has reached port.

The minimum surgery needed to stabilise the patient's condition may be the safest course until the physiological derangement can be corrected. Damage control surgery is restricted to only two goals:

- 1 stopping any active surgical bleeding;
- 2 controlling any contamination.

Once these goals have been achieved, then the operation is suspended and the abdomen temporarily closed. The patient's resuscitation then continues in the intensive care unit. Once the physiology has been corrected, the patient warmed and the coagulopathy corrected, the patient is returned to the operating theatre for any definitive surgery.

Table 28.6 Effect of raised intra-abdominal pressure on individual organ function.

Organ	Effect
Renal	Increase in renal vascular resistance leading to a reduction in glomerular filtration rate and impaired renal function
Cardiovascular	Decrease in venous return resulting in decreased cardiac output because of both a reduction in preload and an increase in afterload
Respiratory	Increased ventilation pressures because of splinting of the diaphragm, decreased lung compliance and increased airway pressures
Visceral perfusion	Reduction in visceral perfusion
Intracranial effects	Severe rises in intracranial pressures

Damage control resuscitation

The concept of damage control has been broadened to include the techniques used in resuscitation as well as in surgery. The time in the emergency department is minimised and the majority of resuscitation of the patient is carried out in the operating room and not in the resuscitation bay (Table 28.7). The resuscitation is individualised through repeated point of care (POC) testing of haemoglobin, acidosis (pH and lactate) and thrombo-elastography to assess clotting, and is therefore directed towards the early delivery of biologically active colloids, clotting products, and whole blood in order to buy time. The physiological disturbances that are associated with the downward spiral of acidosis, coagulopathy and hypothermia in these serious injuries are predicted and attempts are made to avoid them rather than react to them.

Damage control surgery

The decision that damage control surgery is the appropriate course should be made early (Table 28.8) and allows the whole surgical and anaesthetic team to work together to limit the time in surgery and the earliest possible admission of the patient to the intensive care unit. Damage control is a staged process.

The initial focus is haemorrhage control, followed by control and limitation of contamination, achieved using a range of abbreviated techniques including simple ligation of bleeding vessels, shunting of major arteries and veins, drainage, temporary stapling off of bowel, and therapeutic packing.

Following the above, the abdomen is closed in a temporary fashion using a sheet of plastic (e.g. Opsite) over the bowel, an intermediate pack to allow suction, and a further sheet of adherent plastic drape to the skin to form a watertight and airtight seal. Suction is applied to the intermediate pack area to collect

Table 28.7 The stages of damage control surgery.

Stage	
I	Patient selection
II	Control of haemorrhage and control of contamination
III	Resuscitation continued in the intensive care unit
IV	Definitive surgery
V	Abdominal closure

Table 28.8 Indications for damage control surgery.

Anatomical	Inability to achieve haemostasis Complex abdominal injury, e.g. liver and pancreas Combined vascular, solid and hollow organ injury, e.g. aortic or caval injury Inaccessible major venous injury, e.g. retrohepatic vena cava Demand for non-operative control of other injuries, e.g. fractured pelvis Anticipated need for a time-consuming procedure
Physiological (decline of physiological reserve)	Temperature <34°C pH <7.2 Serum lactate >5 mmol/L (N (normal) <2.5 mmol/L) Prothrombin time (PT) >16 s Partial thromboplastin time (PTT) >60 s >10 units blood transfused Systolic blood pressure <90 mmHg for >60 min
Environmental	Operating time >60 min Inability to approximate the abdominal incision Desire to reassess the intra-abdominal contents (directed relook)

abdominal fluid. This technique is known as the 'Vacpac' or 'Opsite sandwich' (Figure 28.10).

As soon as control has been achieved, the patient is transferred to the intensive care unit where resuscitation is continued.

The next stage following damage control surgery and physiological stabilisation is definitive surgery. The team should aim to perform definitive anastomoses, vascular reconstruction and closure of the body cavity within 24–72 hours of injury. However, this must be individualised to the patient, the response to critical care resuscitation, and the progression of injury complexes.

**Figure 28.10** Abdominal closure following damage control surgery.

The abdomen is closed as soon as possible, bearing in mind the risks of ACS. The closure is not without its own morbidity. Successful closure may require aggressive off-loading of fluid and even haemofiltration to achieve this, if the patient will tolerate it. The best situation is closure of the abdominal fascia, or, if this cannot be achieved, then skin closure only. Occasionally, mesh closure can be used, with skin grafting over the mesh and subsequent abdominal wall reconstruction.

Thoracic damage control is conceptually based on the same philosophy. This is that haemorrhage control and focused surgical procedures minimise further surgical insult, and lead to improved survival in the unstable trauma patient. The aim is to control bleeding and limit air leaks using the fastest procedures available to minimise the operative time.

The indications and techniques for emergency thoracotomy have already been described.

Damage control applies equally to the extremities. In this case, it is shunting of blood vessels, identifying and marking damaged structures, such as nerves, fasciotomy and removal of contaminated tissue which are the main tasks. Subsequent definitive management can be carried out at a later stage (Summary box 28.9).

Summary box 28.9

Damage control surgery

- Resuscitation is carried out in the operating theatre using biologically active fluids
- The surgery performed is the minimum needed to stabilise the patient
- The aims of surgery are to control haemorrhage and limit contamination
- Secondary surgery is aimed at definitive repair

INTERVENTIONAL RADIOLOGY

Interventional radiology can be useful in the management of torso trauma as both an investigative and a therapeutic tool for patients with vascular injury. Angioembolisation following

demonstration of ongoing bleeding in splenic and renal injury is a valuable technique.

NON-OPERATIVE MANAGEMENT

Non-operative management is universally preferred for the management of solid organ injury in haemodynamically stable children. Non-operative management of solid abdominal organ injury has rapidly gained acceptance in the management of adults as well. A stable patient and accurate CT imaging are prerequisites for this approach. Failure of non-operative management is uncommon and typically occurs within the first 12 hours after injury. Therefore, if correctly selected, the vast majority of these patients will avoid surgery, require less blood transfusion, and sustain fewer complications than operated patients.

Antibiotics in torso trauma

There is no level 1 evidence to recommend the use of antibiotics for the insertion of chest drains. However, they should be used in all cases of penetrating abdominal trauma.

CHAPTER
29

Extremity trauma

LEARNING OBJECTIVES

To gain an understanding of:

- How to identify whether an injury exists
- The important injuries not to miss
- The principles of the description and classification of fractures
- The range of available treatments
- How to select an appropriate treatment

INTRODUCTION

The objective when treating any injured person is to restore maximum function with minimum risk. So, the first duty is to identify and treat any immediate threats to life. Following the Advanced Trauma Life Support (ATLS) system (see Chapter 24), management of skeletal injuries starts after the primary survey and initial resuscitation have been completed. Very occasionally, the haemorrhage associated with a fracture may be life-threatening. For example, a pelvic injury may require urgent stabilisation, or a major open fracture needs direct pressure to control blood loss.

DIAGNOSIS, DESCRIPTION AND CLASSIFICATION OF INJURY

Missing an injury can be serious, both medically and legally. Table 29.1 contains a list of injuries which are notoriously easy to miss.

Assessment: history and examination

The mechanism of injury and the patient's description of their symptoms will give the first clues to the injuries which are likely to be found. However, if the trauma was severe enough to cause one injury, then there was enough energy to cause more injuries. Therefore, the identification of one injury is not a reason for satisfaction; it is a warning to search for others. Injuries occur in patterns, e.g. a dislocated knee is often associated with a vascular injury, and a head injury may be accompanied by and mask a fractured cervical spine. In 15 per cent of cases in which a spinal fracture has been identified, there is another spinal injury at a separate site. A repeat examination on the 'morning after' ward round is a time for a further secondary survey to search for occult injuries.

In the multiply-injured or obtunded patient, it may not be possible to obtain a history. In this case, a top-to-toe clinical examination in the secondary survey is even more important

Table 29.1 Extremity injuries which are notorious for being missed.

than usual. The patient's pre-injury condition needs to be checked as this may limit recovery.

Principles of investigation

A summary of the available methods of investigation is given in Table 29.2.

For almost 100 years, the mainstay of the orthopaedic surgeon's investigation has been the plain radiograph. Radiographs should include orthogonal views (two views at 90° separation) and, for long bones, should show the joints above and below the

Sir John Charnley, 1911–1982, Professor of Orthopaedic Surgery, the University of Manchester, Manchester, UK. He pioneered the hip replacement operation. In 1962, he moved his practice to Wrightington Hospital, Appley Bridge, which became a place of pilgrimage for young orthopaedic surgeons from all over the world wishing to specialise in hip replacement. In the same hospital, the John Charnley Research Institute was opened by his wife in 1992. In September 2010, the Royal Mail issued a series of stamps commemorating medical breakthroughs. The 60p stamp featured John Charnley's hip replacement operation as an x-ray.

Hugh Owen Thomas, 1834–1891, a general practitioner of Liverpool, UK. He is regarded as the 'founder of orthopaedic surgery', although never holding a hospital appointment preferring to treat patients in their own homes. He introduced the Thomas splint in 1875.

Gavril Abramovich Ilizarov, 1921–1993, orthopaedic surgeon, Kurgan, Western Siberia, Russia. He did not attend school until he was 11 years old as his family was too poor to buy him shoes.

Table 29.2 Investigation modalities.

Modality	Good for	Problems
Plain radiographs	Fractures and dislocations. Easily available	Radiation. Not good for soft tissues
Computed tomography	Bony spinal injury Global view in polytrauma Planning treatment of complex fractures	Radiation dose. Availability. Safety in severe injuries
Ultrasound scan	Soft-tissue injuries	Operator dependency
Magnetic resonance imaging	Soft-tissue problems and fractures	Availability and expensive Difficult to use in the ventilated patient
Bone scan	Stress fractures and tumours	Radiation dose
Fluoroscopy	Checking progress of surgery	Small field of view Quality Image distortion

injury. Other imaging modalities are now being used more frequently. Computed tomography (CT) scans are invaluable for defining more complex patterns of a fracture, particularly adjacent to a joint. They are now also being used for the global assessment of the multiply-injured person. As scan acquisition times decrease and physiological monitoring improves, the dangers for the multiply-injured patient of being isolated in a scanner are reduced and the benefits of accurate diagnosis increased. Ultrasound is used to assess soft-tissue structures, e.g. Achilles tendon or rotator cuff injuries. Magnetic resonance imaging (MRI) is used primarily to show soft-tissue injury, particularly around the knee. Injuries with a reputation for being missed, such as a posterior dislocation of the shoulder (Figure 29.1),

should be actively sought whenever there is any chance that they may be present (Summary box 29.1).

Summary box 29.1

Finding an injury

- Look specifically for 'easily missed injuries'
- Re-examine the multiply injured patient

Achilles, the Greek hero was the son of Peleus and Thetis. When he was a child, his mother dipped him in the Styx, one of the rivers of the Underworld so that he should be invulnerable in battle. The heel by which she held him did not get wet, and was, therefore, not protected. Achilles died from a wound in the heel received at the siege of Troy.

Figure 29.1 Posterior dislocation of the shoulder. (a) Anteroposterior view; (b) origin of the light bulb sign; (c) axial projection demonstrating how much easier it is to visualise the injury on this view; (d) axial projection highlighting this point and further demonstrating the impacted fracture in the humeral head, or Hill-Sachs lesion.

DESCRIPTION AND CLASSIFICATION OF MUSCULOSKELETAL INJURY

Description of injury

The soft-tissue injury

There are two components of soft-tissue injury that need to be identified: the degree of damage to the soft-tissue envelope around the fracture and the integrity of the important structures passing through the area, primarily the arteries and nerves. A fracture is defined as open when the haematoma associated with it is exposed by a breach in an epithelial surface; this is usually skin, but is sometimes mucous membrane of the bowel or vagina. When there is such a wound, it should be described in plain terms, e.g. 'a ragged 6-cm laceration over the anterior aspect of the midshaft of the left tibia with contused skin edges, but no gross contamination'. To minimise contamination, the wound, with a scale beside it, should be photographed and then covered. It should not be disturbed again until definitive treatment is given in an operating theatre.

Even if there is no wound, the damage to the soft-tissue envelope will need describing. There may still be bruising, swelling, contusion, tissue shearing or crushing. Severe soft-tissue swelling may make it wise to delay surgery.

Injuries to arteries and nerves

Major arterial injuries may be limb or life threatening. Distal neurovascular status should always be checked and recorded, especially if there is penetrating trauma, a dislocation or a displaced fracture. This record should be specific, e.g. 'dorsalis pedis present' or 'capillary refill <2 s', not just 'neurovascularly intact'. The warm ischaemia time should be kept to below 4 hours. If the level of the injury is clinically obvious, it is best to proceed immediately to treatment; on-table arteriography can be obtained later if required.

Nerve injuries should be identified and recorded. It is important that if operative treatment of a fracture is planned, the preoperative neurological status is recorded. As with the vascular examination, the findings should be recorded in such a way that they can be interpreted without ambiguity.

Compartment syndrome

Compartment syndrome is discussed in Chapter 32.

The bony injury

The terminology used in this description is illustrated in Figure 29.2. Figure 29.3 shows 'a 45° oblique fracture at the junction of the proximal and middle thirds of the right tibia with an associated fibular fracture'. A good description needs the following components:

- name the injured bone;
- give the region of the bone;
- is the fracture simple or multifragmentary;
- describe the direction of the fracture line: transverse, oblique or spiral;
- are the fragments displaced or undisplaced;
- if displaced, describe the alignment, length and rotation;
- note any evidence of pre-existing pathology;
- any associated joint dislocation.

In adults, the fracture line is generally complete, i.e. it extends

Figure 29.2 Descriptive terms for fractures.

Figure 29.3 Fracture of the shaft of the tibia.

through both cortices. However, in children, the fracture line may be incomplete as the bone is plastic. These fractures are called torus (ring-shaped crumpling) and greenstick (buckling) (Figure 29.4). Compression fractures occur when cancellous bone collapses; an example is a wedge compression fracture of a vertebral body (Summary box 29.2).

Summary box 29.2

Describing an injury

Use plain language to describe:

- Location
- Soft-tissue component
- Bony injury

Figure 29.4 Types of bony injury. (a) Uninjured bone; (b) adult transverse fracture failure across the whole bone; (c) greenstick fracture; the bone has failed on the tension side; (d) torus or buckle fracture; the bone has failed on the compression side.

Classification of injury

Soft-tissue injury

Despite the emphasis placed upon management of the soft tissues, it remains common practice that unless it is an open injury the soft-tissue component of an injury is described and not classified (Summary box 29.3).

Summary box 29.3

The value of classification

- Encourages and directs evaluation of the injury
- Assists planning of treatment
- Guides prognosis
- Results in easier data retrieval
- Allows comparison with the results of other surgeons

Open injuries are generally classified; the system most commonly used is that of Gustilo and Anderson, where the grade of the injury is not determined by the size of the wound alone; thus, a high-energy fracture with a <1-cm wound is a grade III fracture. This means that the injury cannot be finally classified until its full extent is assessed on completion of the initial wound excision. The classification is summarised in Table 29.3.

Bony injury in adults

The AO (*Arbeitsgemeinschaft für Osteosynthesefragen*, literally Working Party on Problems of Bone repair) system provides a principle-based comprehensive classification of fractures. The system is organised to identify the site and nature of a fracture. Initially, the site is identified by two numbers: the first records

Table 29.3 Gustilo and Anderson open fracture classification.

Type	
I	A low energy open fracture with a wound less than 1 cm long and clean
II	An open fracture with a laceration more than 1 cm long without extensive soft tissue damage, flaps or avulsion
III	Characterised by high energy injury irrespective of the size of the wound. Extensive damage to soft tissues, including muscles, skin, and neurovascular structures, and a high degree of contamination. Multifragmentary and unstable fractures
Subgroups of type III	
A	Adequate soft tissue cover of a fractured bone after stabilisation
B	Inadequate soft tissue cover of a fractured bone after stabilisation, i.e. flap coverage required
C	Open fracture associated with an arterial injury requiring repair

Source: Gustilo RB, Mendoza RM, Williams DN. Problems in the management of type III (severe) open fractures: a new classification of type III open fractures. *J Trauma* 1984; **24**: 742–6.

which bone is involved and the second which segment of that bone (Figure 29.5). The classified fracture is recorded as an alphanumeric; for instance, the tibial fracture described at the beginning of this section is a 42A2. The '4' and the '2' are simply shorthand for the tibial shaft. The letter begins to define the nature of the fracture as shown in Figure 29.6; in this case it is a simple or 'A-type' diaphyseal fracture. The final number given refines the record of the fracture pattern; for a simple diaphyseal fracture '1' represents a spiral, '2' an oblique and '3' a transverse fracture. The system goes into further detail but this requires reference to the AO classification book (see Further reading).

Growth plate injuries

The weakest area of a child's bone is the epiphyseal plate and fractures are common here. The physis contains cells that are responsible for longitudinal bone growth. Damage may lead to growth arrest, especially if a bridge of bone (bony bar) forms between the epiphysis and metaphysis.

The classification of Salter and Harris is used to describe the nature of the epiphyseal injury. These patterns of injury are shown in Figure 29.7 and a description of the types and their characteristics is given below:

- Type I, a transverse fracture along the line of the physis; the growing zone is not usually injured so there is no growth disturbance. This fracture is common.
- Type II, similar to a type 1 injury, but the fracture line deviates off into the metaphysis at one end, producing a metaphyseal fragment; this fracture seldom affects growth. This fracture is very common.
- Type III passes along the physis and then deviates into the epiphysis (intra-articular); rarely results in significant

Robert Bruce Salter, 1924–2010, Professor of Orthopaedic Surgery, The University of Toronto, Ontario, Canada. A pioneer in the field of paediatric orthopaedic surgery; received international awards for medical science and the Distinguished Achievement for Orthopaedic Research award.

Figure 29.5 The AO classification system: the first two numbers specify the site of the fracture.

Figure 29.6 The AO classification system: the letter defines the nature of the fracture.

Figure 29.7 The Salter–Harris classification of growth plate injuries.

deformity, but can lead to joint incongruity. This fracture is not common.

- Type IV crosses the physis passing from the epiphysis into the metaphysis; if displaced it interferes with the growing layer of cartilage cells so can cause premature focal fusion of the

physis followed by deformity. This fracture is not common.

- Type V, a crush injury of the physis; associated with growth disturbances at the physis. Diagnosis may be difficult as the radiograph may look normal; however, premature closure of the physis reveals the diagnosis. This fracture is rare.

- Type VI, rare injury consisting of an injury to the perichondral structures by direct trauma, e.g. heat or chemical (Summary box 29.3).

THE RESPONSE TO INJURY

The natural history of a fracture is that the broken bone will heal. However, it may be slow (delayed union) or even fail to unite (non-union), or unite in a poor position (malunion).

Bone healing

Fractures heal by indirect or direct mechanisms:

- **Indirect (secondary) bone healing.** This occurs with a callus precursor and is referred to as enchondral ossification. It tends to occur when the bone ends are not perfectly aligned and when there is some movement at the fracture site during the healing process. Such secondary bone healing is broadly characterised by three main phases: (1) inflammation, (2) repair with callus formation and (3) remodelling of immature woven bone to mature lamellar bone. It may be thought of as the natural way for a bone to heal and takes only weeks to complete.
- **Direct (primary) bone healing.** This occurs without callus formation. It is part of the normal process of remodelling with cutting cones crossing the fracture and new lamellar bone being laid down behind them. It tends to occur when the fracture ends are closely opposed and there is no relative movement between them. This occurs after rigid internal fixation of fractures and takes up to a year to complete.

If fixation of a fracture achieves absolute stability between the fragments, direct healing occurs. This process is slow, but if the construct is strong then the patient can return to most activities quickly and well before the fracture has healed. The amount of movement which occurs between the fracture fragments depends both upon the surgical construct and also on the amount of load applied.

Bone union is not just dependent upon mechanical factors. The healing tissues require an adequate blood supply. At the time of surgery, care must be taken to minimise disruption to the blood supply of the healing tissues.

Adverse outcomes

Malunion

Malunion is when the bone unites in an incorrect position. As a guide, an articular step should not be greater than the thickness of the articular cartilage (2 mm) or premature arthritis will result. In the lower limb, angulation or rotation should not exceed 5°. Visible deformity is seldom acceptable, and malrotation can be very disabling.

Non-union

Non-union of a fracture may be defined as failure to show progressive clinical or radiographic signs of healing. The principle types of non-union are atrophic, hypertrophic and infected. These can be secondary to failure of biology and/or mechanical environment and patient factors (smoking). In atrophic non-union, the problem is often poor blood supply. The fracture gap is filled by fibrous tissue and the bone fragments remain mobile. Hypertrophic union usually occurs when there is excessive

movement at the fracture site, leading to abundant periosteal bone formation. If stability is improved, union is likely.

Infected non-union

Infected non-union merits a separate mention as it is a potentially catastrophic complication. Its treatment is often prolonged, multistaged and can result in loss of the limb. This is why the top priority in open fractures is to prevent contamination from becoming infection.

Delayed union

Delayed union is the term used to describe a fracture that has not healed in the expected time. Fractures in children tend to heal more rapidly than fractures in adults, and upper limb fractures can heal more quickly than lower limb fractures. Fractures in children may unite (the bone ends stick together) within 2–3 weeks and consolidate in 4–6 weeks. Femoral fractures in adults may take 12 weeks to unite and 24 weeks until they are as strong as they were before (consolidation) (Summary box 29.4).

Summary box 29.4

Fracture healing

- **Mechanics.** Movement and strain determines whether bone healing is indirect or direct
- **Biology.** The blood supply needs to be intact or atrophic non-union will result
- **Infection.** Must be avoided at all costs

Understanding outcome

Table 29.4 lists the potential advantages and disadvantages of the range of treatments available for a fracture.

PRINCIPLES OF FRACTURE MANAGEMENT

When planning fracture treatments, the first principle is to consider whether any intervention is necessary; many fractures require only symptomatic treatment. The interventional management of the bony injury has two components: reduction and stabilisation.

Reduction

A fracture can be reduced using closed or open methods. Manipulating a fracture by a closed technique, i.e. without surgically exposing the bone, is an art. The key is to utilise the remaining soft tissues, especially the intact periosteum on the concave side of the fracture; they will tend to guide the bony fragments. The most elegant way of obtaining a good reduction is to reverse the mechanism of the injury. The sequence of injury and reversal is illustrated in Figure 29.8.

At open operation, the bony fragments can be manipulated just as in a closed reduction; it is easier to do because the bony fragments can be watched. The fragments can also be moved by applying clamps directly to the bone. The adequacy of the reduction with a simple fracture pattern can be judged by direct reference to the fracture fragments themselves, just as when solving a simple jigsaw. With more complex fracture patterns, exposure of all of the individual fragments may devitalise them

Table 29.4 Risks and benefits of fracture treatment.

Benefits	Risks
Pain relief	Anaesthesia
Prevention of infection	Introduction of infection
Restoration of anatomy	Damage to soft tissues and neurovascular structures
Early movement of the limb	
Early movement of the patient	Devitalising bone
Improved function	Need for implant removal
Reduced risk of secondary arthritis	Financial cost (cost of treatment)
Financial cost (time off work)	

and so reduction is assessed indirectly by restoring the overall position of the limb. The assessment of the adequacy of fracture reduction may be made by direct viewing of the fracture ends with the naked eye at open operation. Otherwise, the shape of the limb can simply be compared with the opposite side. Reference to Figure 29.2 demonstrates that the fracture with rotational deformity is difficult to depict graphically and for the same reason is often not noticed on radiography or at open surgery. However, merely looking at the whole limb and comparing it with the normal side generally reveals whether the rotational reduction is adequate (Summary box 29.5).

Summary box 29.5

Reduction

- Reduction has two components: reducing the fragments and assessing adequacy of reduction
- Reduction can be performed open or closed
- The principle is to reverse the movement which created the fracture
- Over-angulation allows the intact periosteum to guide the fragments into position

Stabilisation

When a fracture has been reduced it needs to be held or stabilised while healing progresses.

When choosing a technique of stabilisation, the aim is to:

- optimise the biological and mechanical environment to create the most favourable conditions possible for fracture healing;
- minimise the period of disability by speeding healing or creating stability so that function can be allowed during healing.

Absolute stability is generally achieved by precise reduction and compression of the fracture ends. No displacement should occur during the loading permitted in the postoperative period. This provides the environment for direct bone healing. In contrast, **relative stability** will produce a situation that allows some movement in proportion to the load applied. This stimulates callus formation and quick secondary bone healing. Figure 29.9 shows some of the configurations that can be used to achieve relative and absolute stability. Simple fracture patterns allow absolute stability to be obtained; in the more complex fracture patterns, the biological cost of achieving precise reduction (for example,

Figure 29.8 (a–d) Representation of how the mechanism of injury causes the bony and soft-tissue injury. (e–h) Representation of how the residual mechanical properties of the tissues may be used to effect and hold a reduction.

soft-tissue stripping) may outweigh the advantages of struggling to obtain absolute stability.

Methods used for stabilising a fracture

Casting and splinting

A cast may be plaster of Paris or fibreglass. Immediately following a fracture, there may be significant soft-tissue swelling. If the risk of a compartment syndrome is to be avoided, only a backslab (or a split plaster) should be applied until the swelling has peaked out. Even then, the patient may need to be admitted for a period of observation, or instructions given to the patient and family to follow in the event of compromise to the circulation of the limb.

In an unstable fracture (as in Figure 29.9), the cast should be moulded to stabilise the fracture using a so-called ‘three-point fixation’. A plaster achieving this will appear crooked; this leads to the adage that ‘if you want a straight bone then you need a bent plaster’ (Figure 29.10).

The advantages and disadvantages of casting and splinting are described in Table 29.5.

Figure 29.9 How absolute and relative stability can be achieved. The same implants may be used to achieve different mechanical effects.

Traction

Traction is the process of putting a stretching force on a limb to pull a fracture straight. The advantages and disadvantages of traction are given in Table 29.6. It relies on the integrity of the surrounding soft tissues (especially the periosteum) to create the tension which forces the fracture fragments to line up straight. Traction splints are still often used for temporary stabilization of a fracture. The Thomas splint for transporting a patient with a fractured femur is a typical example of static traction, creating tension between two fixed points (Figure 29.11a). Hamilton Russel traction is an example of dynamic traction where the pull is exerted by a system of weights. This tension is balanced against the patient's own body weight, which provides the opposing force but allows the patient to move around in bed (Figure 29.11b).

Table 29.5 Advantages and disadvantages of casting and splinting.

Advantages	<ul style="list-style-type: none"> No wound No interference with fracture site Cheap Adjustable No implants to remove
Disadvantages	<ul style="list-style-type: none"> Limited access to the soft tissues Cumbersome (particularly in the elderly) Interferes with function Poor mechanical stability 'Plaster disease'

Traction can be applied either using the skin (skin traction) or by direct coupling to the bone with pins or wires (skeletal traction). The simplest practical example of traction is the use of a collar and cuff to treat a proximal humeral fracture. As long as the patient is upright, the weight of the elbow and forearm provides the traction. More complex systems of weights, counterweights and pulleys can be used to provide the appropriate force required to maintain alignment of a lower limb fracture. The concept of a controlled and uncontrolled fragment is helpful; failure to understand this can lead to failure of traction.

Open reduction and internal fixation

Open reduction and internal fixation (ORIF) is the term used to describe the operation of reducing a fracture under direct vision and then applying plates, screws, wires or intramedullary nails to hold the reduction.

Table 29.6 Advantages and disadvantages of traction.

Advantages	<ul style="list-style-type: none"> No wound in zone of injury No interference with fracture site Materials cheap Adjustable
Disadvantages	<ul style="list-style-type: none"> Restricts mobility of patient Expensive in hospital time Skin pressure complications Pin site infection Thromboembolic complications

Plaster of Paris is a white crystalline powder, calcium sulphate hemihydrate $\text{CaSO}_4 \cdot 0.5\text{H}_2\text{O}$, which sets hard when water is added to it.

Figure 29.10 (a) The position achieved at the end of the manipulation described in Figure 29.9. (b) Demonstration of how by moulding the cast the intact periosteum is kept under tension and the bone under compression; thus, the remaining mechanical properties are used to achieve stability.

Figure 29.11 (a) Static traction with a Thomas splint. The force and counterforce are contained within a static system. The load is applied to the patient through the tibial traction pin via a cord tightened with a Spanish windlass. The counterforce is applied through pressure by the splint on the ischial tuberosity. (b) A dynamic system in which the load is applied by weights suspended from the tibial pin and the counterforce is the patient's own weight.

Plates and screws

A lag screw is used to compress two things together. This is achieved by drilling the hole under the screw head in the proximal fragment to a diameter which is greater than can be grasped by the threads of the screw. This allows the screw to slide down this hole until the head of the screw impacts against the sides of this hole. The hole in the distal fragment is smaller so that the

thread of the screw grips its walls. Further turning of the screw then results in the screw thread pulling the distal fragment in, so that it is compressed against the proximal fragment (see Figure 29.9a). This is especially useful when a fracture can be reduced precisely. A lag screw can then hold the two fragments together so securely that absolute stability is provided. A single lag screw will provide absolute stability, but may not provide a strong durable fixation. If this is the case, then it may be protected by a neutralisation plate. This is a classic method of stable internal fixation and is ideal for fractures such as those of the radial and ulnar shafts. Compression plates have oval screw holes in them. As the screw head beds in, the plate is forced to slide sideways and to compress the fracture site. This can improve bone contact and stability.

A recent development is the locking plate. Here the screw has a threaded head that tightens into the plate. The screws are not floppy within the plate, but 'lock' when tightened. This gives angular stability similar to that of an external fixator and seems particularly advantageous in elderly bone and at metaphyseal/diaphyseal junctions. Table 29.7 shows the advantages and disadvantages of plate fixation.

Intramedullary nailing

The diaphysis of a long bone is essentially a tube. An intramedullary nail can be inserted down the medulla to hold a fracture reduced. The nail itself is usually made of steel or titanium, and may be solid, hollow or slotted in cross-section. To extend the range of fractures suitable for stabilisation, nails are now made with drill holes at either end; this allows locking of the nail to the bone with further screws to control both rotation and length.

Thin nails can be inserted without reaming or heavier nails can be inserted after reaming. There are pros and cons to both techniques. Table 29.8 summarises this debate.

Standard nails are not suitable for the growing bone where they would transgress and damage a growth plate. The advantages and disadvantages of intramedullary nailing are described in Table 29.9.

External fixation

In external fixation, each side of the fracture is connected to the main fixator which lies outside the patient. The connection of the frame to the bone is via either half-pins (that is, stiff metal rods typically 5–6 mm in diameter) or tensioned wires (typi-

Table 29.7 Advantages and disadvantages of plate and screw fixation.

Advantages	Can be used when anatomical reduction is required
	Allows early mobilisation
	Can provide absolute or relative stability
Disadvantages	May interfere with fracture site
	Periosteal/soft-tissue damage
	Does not normally allow for immediate load-bearing
	Potential for infection
	Metalwork complications
	?Need for plate removal

Advantages	Minimally invasive Early weight-bearing Less periosteal damage than open reduction and internal fixation Seldom need removal
Disadvantages	Increased risk of fat emboli/chest complications Infection difficult to treat Difficult to remove if broken

cally 1.8 mm in diameter), which are then secured to the frame by clamps (see Figure 29.9c). External fixators are quick and relatively simple to apply. A further great advantage of external fixation is that it can be used even if there is soft tissue loss and bone is exposed. Plastic surgeons can work on providing soft tissue cover while the fracture remains stable (Table 29.10). A third advantage of external fixators is that it is possible to modify the mechanical environment of the fracture (compressing, distracting and correcting alignment) without needing to subject the patient to further surgery.

The prime disadvantage of an external fixator is the 'pin sites', i.e. the point where the pins or wires penetrate the skin. These pin sites require care as they may become infected or tether soft tissues, thereby interfering with function.

Specific indications for external fixators include:

- emergency stabilisation of a long bone fracture in the polytrauma patient thought too unwell to have other interventions, 'damage control orthopaedics';
- stabilisation of a dislocated joint after reduction, e.g. a spanning fixator across the knee joint while the vascular surgeons repair an arterial injury with a knee dislocation;
- complex periarticular fractures, temporary stabilisation to allow the soft tissues to settle before definitive fixation, e.g. a distal tibial (pilon) fracture;
- fractures associated with infection;
- treating fractures with bone loss.

A Kirschner wire (also called a K-wire) is a thin, flexible wire made of stainless steel. Transfixing wires can be passed percutaneously to keep fracture fragments reduced. They are cheap and often quick and simple to use. They have been used extensively around the hand and wrist as definitive fixation. Another common use of wires is for temporary fixation intraoperatively. Thus, a provisional reduction can be held with wires while the

more definitive and robust fixation is applied. Some of their uses are shown in Table 29.11.

Flexible wire is also used in fracture fixation. Both patella and olecranon fractures can be fixed using a 'figure-of-eight' tension band. This is a dynamic fixation such that, when a predictable load is applied to the bone, compression across the fracture site is actually increased.

Complications of K-wires are pin-track infection, wire breakage, loss of fixation and migration of the wire. Migration of a wire is a potentially serious problem and, as a consequence, their use in some areas is ill advised. K-wires placed around the clavicle have been known to migrate, penetrating the thoracic cavity and even the heart.

Arthroplasty

Prosthetic replacements may be used for treating articular fractures or those in which avascular necrosis is inevitable (e.g. the subcapital fractured neck of femur). In the proximal humerus, a multifragmentary fracture that is considered unsalvageable by internal fixation methods can be treated with a shoulder hemiarthroplasty.

Table 29.10 Advantages and disadvantages of external fixation.

Advantages	No interference with fracture site Adjustable after application: alignment; biomechanics Soft tissues accessible for plastic surgery Rapid stabilisation of fracture Hardware easy to remove
Disadvantages	Pin site infection Interferes with plastic surgical procedures Soft-tissue tethering Cumbersome for the patient

MANAGEMENT BY TYPE AND REGION

Table 29.12 gives some of the general indications for operative stabilisation. Two simple questions to ask of a fracture are: 'Does it need to be reduced?' and 'Does it need to be held?'

Diaphyseal fractures

The diaphysis is composed predominantly of a tube of dense cortical bone. Fracture treatment is aimed at restoring function by achieving bony union with correction of the length, alignment and rotation. In many diaphyseal fractures, if the bone heals with the adjacent joints in their normal relationship, the anatomical reduction of the fracture fragments at the fracture site is of secondary importance. This is demonstrated in Figure 29.12, which shows C-type fractures treated in this way.

Table 29.12 Indications for surgery in limb trauma (the main indication is that operation will produce a better outcome; the principles are given below).

A fracture requiring treatment that is unsuitable for non-operative measures
Open fractures
Failed non-operative management
Multiple injuries
Pathological or impending pathological fractures
Displaced intra-articular fractures
Fractures through the growth plate, where arrest is possible (Salter-Harris type III–V)
Avulsion fractures that compromise the functional integrity of a ligament/tendon around a joint (e.g. olecranon fracture)
Established non-unions or malunions

Femoral shaft fractures

The anatomy of the proximal femur allows easy access to the medullary canal for inserting an intramedullary device nail. A statically locked intramedullary nail is suitable for the vast majority of adult femoral shaft fractures irrespective of their pattern. With an isolated femoral shaft fracture, the patient can be expected to mobilise rapidly postoperatively and may only be hospitalised for a few days.

Traction was traditionally used as the definitive treatment for these fractures and treatment took 12–16 weeks. Now traction is only used as a first aid measure to provide pain relief and maintain length while transferring a patient to definitive care.

Tibial shaft fractures

When the fracture is sufficiently stable, generally an A-type pattern, casting is the safest and cheapest choice. A full-leg cast is applied immediately and split to the skin. Once the risk of compartment syndrome has passed, the cast is closed. By 4 weeks, it can generally be changed to a moulded, patella tendon-bearing, below-knee cast. This allows the knee to move. Cast treatment requires frequent and careful monitoring and there should be no hesitation in changing the cast should the reduction be deteriorating. To correct minor deformity in a controlled and comfortable manner, the cast may be wedged.

Surgery to a tibial shaft fracture is often indicated either as a result of instability (B- or C-type fractures) or because the patient also has other injuries. Currently, intramedullary nailing is the most frequent choice of treatment, but there is a high incidence of anterior knee pain following this operation, and so it should be used with caution in those patients who have to kneel. Malunion is common in nailed fractures of the proximal tibial shaft; so plating is a better option for fractures which are closer to the metaphysis. External fixation remains a good option for a wide range of tibial shaft fractures. The subcutaneous position of the tibia makes pin placement and pin site care relatively straightforward.

Humeral shaft fractures

In humeral shaft fractures, the maintenance of limb length and alignment is nowhere near as important as in the leg. Thus, the majority of humeral shaft fractures can be treated non-opera-

tively with a simple protective functional brace and a collar and cuff. This is the safest and cheapest option. The indications for operative management include an open fracture, the presence of other injuries such as head injury, multiple injuries, ipsilateral arm fractures and failed non-operative management. In these circumstances, fixation and stability can be achieved by either plating or intramedullary nailing. The rate of non-union is significantly higher when nailing the humerus than when nailing the femur or tibia; thus, plating is generally the treatment of choice. Figure 29.13 shows a plated B-type diaphyseal fracture. Should the need for fixation be combined with signs of radial nerve damage, plating has the advantage of allowing exploration of the nerve.

Radius and ulna

Although the radius and ulna appear outwardly similar to other long bones, they can best be visualised as the two components of a large joint. Their relationship requires precise anatomical restoration if they are to function normally in supination and pronation. This precision is best and most easily achieved by open reduction and plate fixation (Summary box 29.6).

Summary box 29.6

Diaphyseal fractures

- Restore length, alignment and rotation
- Consider whether primary or secondary bone healing is the objective
- Radius and ulna need precise reduction to function

Metaphyseal fractures

Fractures in the metaphyseal region are classified as A-type if they are extra-articular, B-type if they are partial articular and C-type if they are complete articular.

In an A-type fracture, the joint surfaces remain intact, so congruity is not an issue. Therefore, the problem may be thought of as being similar to that of treating a diaphyseal fracture; however, there are two differences that need attention. First, the injury and the subsequent treatment, being close to a joint, are more liable to cause joint stiffness. Second, the bone on either side of the fracture is not of a similar type or quality. It is generally easier to obtain a mechanical hold on the diaphyseal bone of the shaft than on the spongy bone of the metaphysis; thus the quality of fixation may be imbalanced. This imbalance in fixation is even more apparent when dealing with osteoporotic bone and can easily lead to fixation failure.

With B- and C-type fractures, the joint surfaces themselves are involved. Thus, in addition to providing stability and overall alignment, the congruity of the joint surface is also important.

In an A-type metaphyseal fracture, the emphasis is on maintaining length, alignment and rotation, while allowing continued function. This requires sound fixation as demonstrated in Figure 29.14. In this instance, the fixation has been achieved with a plate and screws, but it could equally have been carried out with an external fixator.

In a B-type partial articular fracture joint, congruity is the prime objective. This can often be maintained with relatively lightweight fixation as the load borne by the metalware itself is

Figure 29.12 (a) and (d) are C-type or segmental tibial fractures. Each was a high-energy injury. (b) and (e) show a temporary spanning external fixator applied in each case. (c) and (f) show definitive relative stability was achieved with different methods of bridging fixation. Healing was by indirect means in both cases. Despite irregularities at the fracture sites the overall position was satisfactory and function was good.

low (Figure 29.15). B-type fractures, when they require surgery, are nearly always treated with screws, or screws and plates.

The C-type or complete articular fracture combines both of these features. They need joint congruity and bone alignment. This is demonstrated in the tibial plateau in Figure 29.16. The articular component of the fracture is generally held with screws, allowing for interfragmental compression. The metaphy-

seal component of the fracture may be held as in the A-type fracture, with plates and screws or an external fixator.

Distal radial fractures

Because of the frequency of their occurrence, distal radial fractures deserve separate mention. The common fractures in this area are A-type, i.e. extra-articular. The Colles fracture

Figure 29.13 A B-type humeral shaft fracture. This fracture could not be controlled by non-operative means and was treated with lag screws protected by a plate.

Figure 29.14 An A-type or extra-articular metaphyseal fracture. A plain lateral radiograph of this Smith-type fracture (a and b). Fracture fixed to a plate. There is no interfragmental compression. The plate is pushing against or buttressing the distal fragment (c and d).

with dorsal and radial angulation can generally be treated by manipulation and casting. When this does not provide sufficient stability, a useful technique to have available is intrafocal wiring, popularised by Kapandji. In this technique, the wires are placed through the fracture site, then angled to stabilise the distal fragment and secured through the opposite cortex of the proximal fragment (Figure 29.17).

When the displacement is in the opposite direction, i.e. volar, the so-called Smith's fracture, stability is difficult to achieve by casting, and so plating is generally employed.

When there is significant articular displacement of a distal radial fracture, formal open reduction and fixation with plates and screws is being performed in a very similar fashion to dealing with a tibial plateau fracture, but with smaller implants.

Ankle fractures

The eventual functional outcome of ankle fractures depends upon the position of union. Thus, if the fracture is stable, it requires only symptomatic treatment. An unstable ankle fracture

requires reduction and maintenance of reduction until bony union. The maintenance of reduction is more reliable with operation and so in the younger patient this is generally the preferred option. In the elderly, there is no clear evidence for choosing between operative and non-operative management.

Managing fractures in the skeletally immature

Many injuries are dealt with in an analogous way in the child and the adult; however, there are naturally differences. As discussed in Chapter 23, there needs to be constant vigilance for evidence of non-accidental injury.

Children's fractures heal more rapidly than those of adults. Remodelling is also possible, so a position which may not be acceptable in an adult may turn out to give a good result in a child. The nearer the fracture is to the growth plate, the greater the remodelling capacity. Deformity is more acceptable in the plane of motion of the adjacent joint. Remodelling is greatest at the ends of the bone that contribute most to longitudinal

Figure 29.15 A B-type or partial articular fracture. (a) Plain radiograph; (b) computed tomography clarifies the injury; (c) fixation with plate and screws achieving compression across a previously reduced fracture.

Figure 29.16 (a) A C-type proximal tibial articular fracture, i.e. none of the joint remains attached to the diaphysis. (b) The small plate and screws (AA) are used to compress the joint fragments, aiming for absolute stability. The heavy duty fixed angled device (BB) spans the fracture and provides relative stability.

Figure 29.17 (a) A displaced distal radial fracture. (b) A wire is introduced percutaneously by hand through the fracture site. (c) The fracture is manipulated into a reduced position (not levered using the wire). Once reduced, the wire is advanced under power into the opposite cortex, securing the reduction.

growth. For example, fractures at the distal femur have more potential to remodel than proximal femoral fractures. Significant remodelling is also expected at the proximal humerus (70 per cent of longitudinal growth). Young children have the greatest capacity to remodel.

Repeated attempts to reduce a physal fracture may injure the physis, and so lead to growth arrest. Internal fixation should not cross the physis, but if this is absolutely necessary, the smallest and smoothest pin should be used.

Trauma is the most common cause of physal arrest, and occurs when a bony bridge forms between the metaphysis and epiphysis. Complete arrest is most commonly seen after a crush injury to the growth plate (Salter-Harris type V). The most common area for growth arrest is the distal femur, proximal and distal tibia and the distal radius.

The thicker and stronger periosteum in children contributes both to fracture stability and to fracture reduction if some of it (known as the 'periosteal hinge') remains intact on the compression side of the fracture.

Children rarely experience non-union and heal their fractures more rapidly than adults. In general, the rate of healing is inversely proportional to age. Complications unique to childhood include growth arrest, progressive angular or rotational deformity and overgrowth of a long bone (post-femoral fracture).

The indications for operative intervention are fewer in children than adults (see Figure 29.26c below under Pathological failure). The generally benign natural history of children's fractures means that the risk of complications often does not balance favourably against a small potential advantage.

Specific injuries

Distal radial fracture

The most common area of fracture in children is the distal radius. Fractures proximal to the growth plate may be treated symptomatically or by manipulation under anaesthesia (MUA). There is no clear rule as to the amount of deformity that can be accepted. As puberty approaches, fractures should be treated as for the adult.

A special case is when the distal radial fracture is sufficiently displaced to require manipulation while the ulna itself is intact. Secondary redisplacement is common under these circumstances and it is advisable to hold the radius with primary K-wiring. When the growth plate is involved in a distal radial fracture, it is generally a Salter-Harris type I or II injury. MUA and casting is usually adequate and growth disturbance is uncommon after primary treatment; however, should the fracture reduction be lost, one should try not to proceed to a second manipulation. The second manipulation is much more likely to cause damage to the physis and subsequent growth problems.

Distal humeral (supracondylar) fracture

The markedly displaced supracondylar fracture is associated with two main complications: (1) neurovascular compromise may occur early and (2) residual deformity is a late complication. The treatment of the former is early reduction, as the bone spike protruding from the proximal fragment may actually be pressing on the structures. Even when the brachial artery itself is involved, there is usually adequate distal flow from the collateral vessels provided so arterial repair is seldom necessary.

The late complication of a supracondylar fracture is deformity. This is due not to an interference with growth (the fracture is proximal to the growth plate), but to poor initial reduction or loss of reduction. As noted above, deformity in the plane of the adjacent joint tends to correct satisfactorily. It is the varus/valgus angulatory deformity that is critical at the elbow. This is very difficult to assess initially as the deformity only becomes obvious once full extension is regained, which may be many months later.

A minimally displaced supracondylar fracture is a benign injury and can be treated symptomatically. When a displaced fracture can be manipulated into a satisfactory position, it sometimes appears stable as soon as the elbow is put in flexion. It is tempting to leave this injury in a flexed cast for stability. If a supracondylar fracture needs to be reduced, it should then be held with K-wires.

Lateral condylar mass fracture of the elbow

This injury is easily missed and is an example of the apparently benign injury that may have significant morbidity if it goes unrecognised. Clinically, the clue is localised lateral tenderness. The radiograph may show just a flake off the distal humeral metaphysis above the capitellum as the bulk of the fracture lies within cartilage which has not yet ossified (Figure 29.18). However, this is an intra-articular fracture that crosses the growth plate. If it is displaced or unstable, it should be primarily fixed. An injury of this nature that is missed can progress to non-union or malunion with growth arrest, or, if an attempt is made to reduce the fracture late under direct vision, it may develop avascular necrosis.

Slipped upper femoral epiphysis

This injury is readily missed. A painful hip in a child approaching puberty should arouse suspicion. The injury can be diagnosed on plain radiography as seen in Figure 29.19. When treated in its early stages, the outcome is excellent; if it progresses to a more severe slip, then the outcome is poor. It is frequently bilateral.

Femoral shaft fracture

Femoral shaft fractures in children can be managed with traction as the short time to union makes this a reasonable choice providing that there is not an accompanying head injury or other long bone fracture. With children under 12–15 kg, simple gallows traction is appropriate. Here the legs are suspended vertically with the buttocks just off the bed. This maintains an adequate position for the fracture, and nappy changes are straightforward. With older children, operative fixation has become more attractive. Standard intramedullary nailing poses a risk to the proximal growth plate and should be avoided in girls below 12 years and boys below 14 years. Flexible intramedullary nails may be placed to avoid the growth plate (Figure 29.20).

Tibial shaft fracture

In a child with an unstable tibial fracture that is not amenable to cast management, external fixation, elastic nailing and plating are all reasonable options (Summary box 29.7).

Summary box 29.7

Fractures in the skeletally immature

- Do not forget non-accidental injury
- Be reluctant to remanipulate a physal injury
- Elastic nails are a significant step forward in fracture treatment in children
- Not many fractures require operative intervention in children

Osteoporotic fractures

In osteoporosis, there is a decrease in bone mass and strength. Eventually, a relatively minor accident can cause a fracture (fragility fracture). These fractures, occurring mainly in the elderly, constitute the bulk of the orthopaedic trauma workload of a UK hospital. The elderly have less capacity to tolerate an injured limb and, thus, it is often not possible for them to partially weight-bear. Therefore, if treatment is to allow them to function, fixation must be able to tolerate full weight-bearing.

Internal fixation in osteoporotic bone remains a challenge. The hold of screws inserted into the bone is often poor. This leads to 'backing out' of the screws and subsequent loss of fracture reduction. Locking plates may help to overcome this problem. In a locking plate construction, the integrity of the structure depends also upon the tightness of the screw in the plate rather than just the tightness of the screw in the bone (Figure 29.21b).

The need for early restoration of function in the elderly makes intervention more attractive, although care must be taken because of wound healing problems.

Intra-articular fractures

It is not always necessary to obtain a perfect anatomical reduc-

Figure 29.18 Lateral condylar mass fracture. (a) Plain radiograph showing the metaphyseal fracture. (b) The yellow shows the shape of the distal humerus including the cartilaginous analogue, and the red shows the true extent of the injury, i.e. a significant intra-articular fracture.

tion of an intra-articular fracture in an elderly osteoporotic patient, and it is even more difficult to hold it. The long-term complication of post-traumatic arthritis is of relatively less importance in the elderly. Thus, in dealing with a tibial plateau fracture in an older patient, the object of operative fixation is different from that in the younger person; it is primarily stability and not congruity that is required. The first stage of an operation to treat a tibial plateau fracture in the elderly is an examination under anaesthesia. If the joint is stable, then there is no indication for operative treatment even though there may be joint incongruity. When a reconstruction is required, bone grafting

Figure 29.19 Slipped left upper femoral epiphysis. (a) Plain radiograph; (b) the injury highlighted.

may be needed as the patient's bone will be crushed. Figure 29.22a shows a case in which bone substitute has been used to help support the reduced joint surface.

Figure 29.20 Femoral shaft fracture in a child, which has been stabilised with elastic nails.

Proximal femoral fractures

Proximal femoral fractures fall into two groups: extracapsular and intracapsular. The blood supply to the femoral head and neck travels down through the hip capsule and then back up the femoral neck. Fractures of the femoral neck inside the capsule (intracapsular or subcapital) are liable to sever the blood supply to the head of the femur and so need to be treated differently to those outside the capsule.

Extracapsular fracture

Biological fixation principles are used to fix this type of fracture. Indirect reduction using a traction table is followed by fixation with a dynamic hip screw (DHS) placed using an image intensifier. The dynamic nature of the implant (the screw slides on the plate) allows the fragments to impact together when the patient walks, as shown in Figure 29.22. This stimulates healing while improving stability and protects the femoral head from penetration by the implant.

Intracapsular fracture

Most patients presenting with an intracapsular (subcapital) fractured neck of femur are elderly and osteoporotic. Early mobilisation offers their best chance of sustaining such independence as they have. However, if the fracture has displaced, then the femoral head will be likely to have lost its blood supply. Fixing it back in place will be fruitless as the bone is dead (avascular necrosis). Therefore, the treatment of choice is to simply replace the compromised femoral head with an artificial head (a hemi-arthroplasty). This treatment is not ideal in younger patients, where the chances of the femoral head being viable is much higher, especially if the fracture is relatively undisplaced (Summary box 29.8). The alternatives for the younger patient are:

- attempt to reduce and fix the fracture holding with screws placed under image intensifier control. Some of these fixations will be successful, but if they fail a total hip replacement is the salvage option.

or

- to perform a primary total hip replacement. This is a mechanically sounder but a more extensive procedure and has a limited life span before it will need revising.

Figure 29.22 (a) A dynamic hip screw for fixing a trochanteric proximal femoral fracture. This allows for compression at the fracture site on load-bearing and protects the femoral head from penetration by the screw when the osteoporotic bone settles. (b) Insert to show the sliding screw in the barrel.

Summary box 29.8

Osteoporotic fractures

- Fragility fractures in the elderly are the most common cause of trauma admission
- The elderly do not tolerate immobility so need secure fixation to allow early mobilisation
- Inter-trochanteric fractures need a dynamic hip screw for an unstable fracture
- Subcapital fractures usually need a hemi-arthroplasty as the blood supply of the femoral head is lost

Injuries to the foot and hand

Foot injuries

Calcaneal fractures

The os calcis is the largest and most frequently fractured hind-foot bone. The most common cause of injury is a fall from a height. Associated injuries include lumbar spine and lower extremity fractures, which occur in 10–20 per cent of cases. Plain radiographs do not clearly show the degree of damage, and CT is necessary for a proper evaluation. Figure 29.23 shows an intra-articular fracture of the os calcis. When accurate reduction and fixation is achieved, surgery is valuable in improving function and reducing pain. However, a good reduction is often difficult to achieve, and the results are then no better than treating the fracture in plaster.

Talus fractures and dislocations

The talus consists of three parts (head, neck and body). It articulates superiorly with the distal tibia and inferiorly with the calcaneus and navicular. The talus has no muscular or tendinous attachments and therefore its blood supply is tenuous. Talar neck fractures are the most common injury and are usually high energy (historically termed 'aviator's astragalus'). A significant complication of this fracture is avascular necrosis of the talus. The goal of treatment is anatomical reduction and stable fixation, as this is thought to reduce the risk of osteonecrosis. Hawkins' sign can be seen approximately 6–8 weeks after injury on plain radiographs. This appears as subchondral lucency of the talar dome, which signifies bony reabsorption. This can only occur if the bone is viable.

Tarsometatarsal (Lisfranc) joint injuries

The tarsometatarsal joint is a very strong weight-bearing structure. It requires significant force to injure it. Poorly treated injuries of this joint can give rise to long-term debilitating symptoms. Once suspected, the injury is then confirmed on plain radiography and delineated further with CT. The treatment of the displaced injury is open reduction and internal fixation.

Achilles tendon rupture

Up to 20 per cent of these injuries are missed at initial presentation. The typical history of a sensation of being kicked behind the ankle while playing sport is frequently given. Sometimes, there is a palpable gap. Simmonds' test (squeezing the calf to produce passive plantar flexion of the ankle) is usually positive.

Figure 29.23 Axial (a) and sagittal (b) views of a displaced intra-articular fracture of the os calcis. (c and d) Intraoperative views of the reconstruction. Both the overall shape and the articular surface have been restored.

The differential diagnosis is an intra-substance tear of the gastrocnemius muscle. In this case, Simmond's test is painful and negative (the foot moves with calf pressure). The diagnosis is confirmed using ultrasound. If the gap separating the torn ends is small, the patient can be treated with serial plasters (starting in equinus and bringing the ankle up to neutral). In patients with a wider gap (>5 mm), a percutaneous repair can be performed.

Hand injuries

Scaphoid fracture

The scaphoid is made up of the proximal and distal poles, a tubercle and the waist. The proximal pole is completely intra-articular and receives all of its blood supply from the distal branches of the radial artery. This enters the scaphoid in a retrograde fashion (distal to proximal). Therefore, fractures across the waist of the scaphoid are most at risk of non-union or avascular necrosis. In contrast, distal pole fractures tend to heal without problems. Figure 29.24 shows a scaphoid fracture and demonstrates how awkward it can be to make the diagnosis on standard anteroposterior and lateral views of the wrist.

The scaphoid is the most commonly injured carpal bone. The mechanism of injury is typically a fall onto the out-

stretched hand with the wrist in radial deviation and dorsiflexed. Fractures of the scaphoid waist occur most frequently. Examination usually reveals tenderness in the anatomical snuff-box. The suspected diagnosis is initially based on clinical findings. Plain radiographs may not show a fracture line for up to 10 days. Therefore, a patient with an equivocal examination has the wrist and thumb immobilised in a cast to reduce the risk of non-union and subsequent avascular necrosis. A repeat clinical and radiographic assessment should be performed between 10 and 14 days post-injury. If a fracture line is now seen, then the cast is reapplied for a further 6 weeks. If the radiographs are normal but clinical suspicion remains, further imaging using a bone scan or MRI should be performed. Open reduction (using a compression screw) is required for unstable fractures (>1 mm displacement or angulation). Complications of scaphoid fractures include non-union, avascular necrosis, malunion and carpal instability.

Lunate dislocation

The lunate forms a part of the proximal row of the carpus with the scaphoid and triquetrum. Articulating with the radius, this row forms the radiocarpal joint.

Figure 29.24 Scaphoid fracture. (a) Anteroposterior and lateral views in which the injury is difficult to see. (b and c) Oblique views with the fracture line highlighted. (d) In this case of a young patient, the fracture was treated with early fixation.

The lunate resides in the concavity of the lunate fossa of the distal radius. Interosseus ligaments hold it to the adjacent scaphoid and triquetrum.

Perilunate dislocations are often unrecognised. Clinical examination reveals significant swelling of the entire carpus. In the absence of a fracture on x-ray, this is diagnostic of carpal dissociation. The diagnosis is made with plain radiographs, but these can be difficult to interpret (Figure 29.25); the lateral view demonstrates the 'spilled tea cup sign' with volar tilt of the lunate. Acute injuries may be initially treated with closed reduction and casting. Irreducible or unstable injuries require open reduction and stabilisation with K-wires. Note that associated injuries, such as scaphoid and radial styloid fractures, as well as median nerve injury, should be excluded.

Thumb metacarpophalangeal ulnar collateral ligament

The integrity of this ligament is important for effective lateral key pinch. Injury to the ulnar collateral ligament is commonly referred to as 'gamekeeper's thumb' or 'skier's thumb', and is caused by the thumb being forced laterally away from the rest of the hand. Tenderness is located on the ulnar aspect of the metacarpophalangeal joint. To assess the integrity of the ligament, perform a stress test.

Figure 29.25 Perilunate dislocation. (a) A plain lateral radiograph of the wrist. (b) The outline of the perilunate dislocation is highlighted. Cap, capitate; Lun, lunate; Rad, radius.

Cast immobilisation can be used in the treatment of partial tears with a good endpoint. A complete tear with instability (excessive opening of the joint when compared with the other side), or a displaced fracture, requires open repair as the ends of the ruptured ligament may become separated by the aponeurosis of adductor pollicis so that natural healing cannot take place (Stener lesion).

Pathological failure

When abnormal bone gives way under normal load, this is referred to as a pathological fracture. Examples include primary bone tumours and bony metastases, osteomyelitis, metabolic bone disease (osteomalacia, Paget's disease, osteoporosis) and haematopoietic disease (myeloma, lymphoma, leukaemia).

The typical history is of a minor trauma. This alerts the surgeon to the possibility of an underlying bony pathology. Blood tests, a chest radiograph and full-length views of the fractured bone are essential. A bone scan is the most sensitive detector of skeletal disease.

In a patient with a primary bone tumour, treatment must be planned to avoid disseminating the disease (see Chapter 39). In a patient who has multiple metastases and whose life span is limited, treatment is aimed at regaining immediate mobility and relief of pain. As can be seen in Figure 29.26, there is a clear rationale for aggressive treatment to restore function despite the risks. The goals of surgical treatment are to reduce pain and to splint the bone so that the patient can use it. Femoral, tibial and humeral fractures are nailed where possible. Some juxta-articular fractures that would require protection if treated with ORIF and bone grafting may be mobilised earlier if bone cement is substituted for the graft. Prophylactic stabilisation should be considered in patients with metastases where there has been cortical bone destruction of ≥ 50 per cent or a femoral lesion longer than 2.5 cm, pathological fracture of the lesser trochanter and persistent pain after irradiation (Summary box 29.9).

Summary box 29.9

Pathological failure

- Do not operate on what might be a primary tumour without careful thought
- Fractures through secondary tumours are treated aggressively to optimise early function

CONCLUSION

The management of extremity trauma is in theory quite straightforward. The first step is to realise that an injury exists as a missed injury cannot be treated. The injury then needs to be understood; this generally involves description and classification. When there is clear evidence as to the best method of treatment for a particular injury, this should be followed. When such evidence is lacking, as is generally the case, the treatment of fractures is generally principle based (Summary box 29.10).

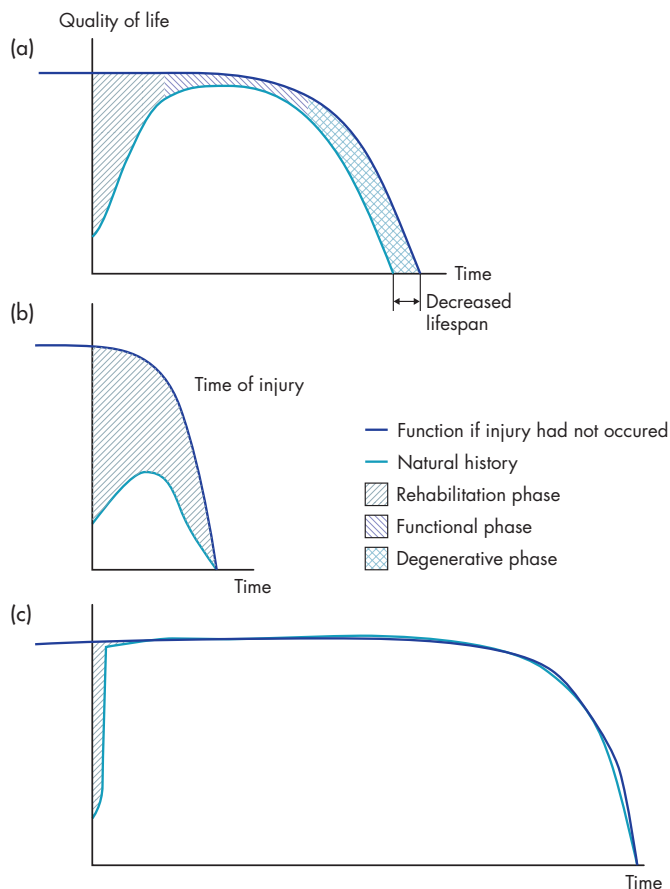

Figure 29.26 Comparative outcome curves for a normal adult (a), pathological fracture (b) and paediatric fracture (c). (a) The generic outcome curve for a patient with a life expectancy of >20 years. There is a rehabilitation, functional and degenerative phase to consider. (b) It is seen that the short life expectancy of a patient with a pathological fracture secondary to metastases means that only the rehabilitation phase is relevant. The patient must be able to function before bone healing. This justifies aggressive treatment. (c) The paediatric fracture with benign natural history. Any marginal early gain has to be considered in the light of great potential for long-term detriment should there be complications.

Summary box 29.10

Summary of extremity trauma

- Realise that an injury exists
- Find the characteristics of the injury, describe and classify it
- Consider the natural history of the injury
- Treatment is guided by outcome if known or by principle if not
- Beware of injuries that are 'easily missed'

CHAPTER 30

Burns

LEARNING OBJECTIVES

To assess:

- The area and depth of burns

To understand:

- Methods for calculating the rate and quantity of fluids to be given

- Techniques for treating burns and the patient
- The pathophysiology of electrical and chemical burns

INTRODUCTION

The incidence of burn injury varies greatly between cultures. In the United Kingdom (with its population of 65 million), each year around 175 000 people visit accident and emergency (A&E) departments suffering from burns, of whom about 13 000 need to be admitted. About 1000 have severe burns requiring fluid resuscitation, and half of the victims are under 16 years of age.

The majority of burns in children are scalds caused by accidents with kettles, pans, hot drinks and bath water. Among adolescent patients, the burns are usually caused by young males experimenting with matches and flammable liquids. In adults, scalds are not uncommon, but are less frequent than flame burns. Most electrical and chemical injuries occur in adults. Cold and radiation are very rare causes of burns. Associated conditions in adults, such as mental disease (attempted suicide or assault), epilepsy and alcohol or drug abuse, are underlying factors in as many as 80 per cent of patients with burns admitted to hospital in some populations.

Legislation, health promotion and appliance design have reduced the incidence of burns, with regulations regarding flame-retardant clothes and furniture, the promotion of smoke alarms, the design of cookers and gas fires, the almost universal use of cordless kettles and the education of parents to keep their hot water thermostat to 60°C all playing their part (Summary box 30.1).

Summary box 30.1

Prevention of burns

A significant proportion of burns can be prevented by:

- Implementing good health and safety regulations
- Educating the public
- Introducing of effective legislation

The last 50 years have seen great strides made to reduce both morbidity and mortality from burn injuries. The coming years

will see a better understanding of the control of physiology along with improvements in reconstruction and rehabilitation.

A large burn injury will have a significant effect on the patient's family and friends and the patient's future. The importance of multidisciplinary care needs to be stressed for the adequate and effective care of the burn patient.

THE PATHOPHYSIOLOGY OF BURN INJURY

Burns cause damage in a number of different ways, but by far the most common organ affected is the skin. However, burns can also damage the airway and lungs, with life-threatening consequences. Airway injuries occur when the face and neck are burned. Respiratory system injuries usually occur if a person is trapped in a burning vehicle, house, car or aeroplane and is forced to inhale the hot and poisonous gases (Summary box 30.2).

Summary box 30.2

Warning signs of burns to the respiratory system

- Burns around the face and neck
- A history of being trapped in a burning room
- Change in voice
- Stridor

INJURY TO THE AIRWAY AND LUNGS

Physical burn injury to the airway above the larynx

The hot gases can physically burn the nose, mouth, tongue, palate and larynx. Once burned, the linings of these structures will start to swell. After a few hours, they may start to interfere with

the larynx and may completely block the airway if action is not taken to secure an airway (Summary box 30.3).

Summary box 30.3

Dangers of smoke, hot gas or steam inhalation

- Inhaled hot gases can cause supraglottic airway burns and laryngeal oedema
- Inhaled steam can cause subglottic burns and loss of respiratory epithelium
- Inhaled smoke particles can cause chemical alveolitis and respiratory failure
- Inhaled poisons, such as carbon monoxide, can cause metabolic poisoning
- Full-thickness burns to the chest can cause mechanical blockage to rib movement

Physical burn injury to the airway below the larynx

This is a rare injury as the heat exchange mechanisms in the supraglottic airway are usually able safely to absorb the heat from hot air. However, steam has a large latent heat of evaporation and can cause thermal damage to the lower airway. In such injuries, the respiratory epithelium rapidly swells and detaches from the bronchial tree. This creates casts, which can block the main upper airway.

Metabolic poisoning

There are many poisonous gases that can be given off in a fire, the most common being carbon monoxide, a product of incomplete combustion that is often produced by fires in enclosed spaces. This is the usual cause of a person being found with altered consciousness at the scene of a fire. Carbon monoxide binds to haemoglobin with an affinity 240 times greater than that of oxygen and therefore blocks the transport of oxygen. Levels of carboxyhaemoglobin in the bloodstream can be measured. Concentrations above 10 per cent are dangerous and need treatment with pure oxygen for more than 24 hours. Death occurs with concentrations around 60 per cent.

Another metabolic toxin produced in house fires is hydrogen cyanide, which causes a metabolic acidosis by interfering with mitochondrial respiration.

Inhalational injury

Inhalational injury is caused by the minute particles within thick smoke, which, because of their small size, are not filtered by the upper airway, but are carried down to the lung parenchyma. They stick to the moist lining, causing an intense reaction in the alveoli. This chemical pneumonitis causes oedema within the alveolar sacs and decreasing gaseous exchange over the ensuing 24 hours (Figure 30.1), and often gives rise to a bacterial pneumonia. Its presence or absence has a very significant effect on the mortality of any burn patient.

Mechanical block on rib movement

Burned skin is very thick and stiff, and this can physically stop the ribs moving if there is a large full-thickness burn across the chest.

Figure 30.1 The swelling that occurs with inflammation due to burns.

INFLAMMATION AND CIRCULATORY CHANGES

The dangers to the airway and respiration described above are readily apparent, but the cause of circulatory changes following a burn are more complex. The changes occur because burned skin activates a web of inflammatory cascades. The release of neuropeptides and the activation of complement are initiated by the stimulation of pain fibres and the alteration of proteins by heat. The activation of Hageman factor initiates a number of protease-driven cascades, altering the arachidonic acid, thrombin and kallikrein pathways.

At a cellular level, complement causes the degranulation of mast cells and coats the proteins altered by the burn. This attracts neutrophils, which also degranulate, with the release of large quantities of free radicals and proteases. These can, in turn, cause further damage to the tissue. Mast cells also release primary cytokines such as tumour necrosis factor alpha (TNF- α). These act as chemotactic agents to inflammatory cells and cause the subsequent release of many secondary cytokines. These inflammatory factors alter the permeability of blood vessels such that intravascular fluid escapes. The increase in permeability is such that large protein molecules can also now escape with ease. The damaged collagen and these extravasated proteins increase the oncotic pressure within the burned tissue, further increasing the flow of water from the intravascular to the extravascular space (Figure 30.2).

The overall effect of these changes is to produce a net flow of water, solutes and proteins from the intravascular to the extravascular space. This flow occurs over the first 36 hours after the injury, but does not include red blood cells. In a small burn, this reaction is small and localised but, as the burn size approaches 10–15 per cent of total body surface area (TBSA), the loss of intravascular fluid can cause a level of circulatory shock. Furthermore, once the area increases to 25 per cent of TBSA, the inflammatory reaction causes fluid loss in vessels remote from the burn injury. This is why such importance is

Figure 30.2 A scald burn (a) and its laser doppler image (b) showing burn depth. Red and pink areas are superficial burns, which should heal with conservative dressings.

attached to measuring the TBSA involved in any burn. It dictates the size of inflammatory reaction and therefore the amount of fluid needed to control shock (Summary box 30.4).

Summary box 30.4

The shock reaction after burns

- Burns produce an inflammatory reaction
- This leads to vastly increased vascular permeability
- Water, solutes and proteins move from the intra- to the extravascular space
- The volume of fluid lost is directly proportional to the area of the burn
- Above 15 per cent of surface area, the loss of fluid produces shock

OTHER LIFE-THREATENING EVENTS WITH MAJOR BURNS

The immune system and infection

The inflammatory changes caused by the burn have an effect on the patient's immune system. Cell-mediated immunity is significantly reduced in large burns, leaving them more susceptible to bacterial and fungal infections. There are many potential sources of infection, especially from the burn wound and from the lung if this is injured, but also from any central venous lines, tracheostomies or urinary catheters present.

Changes to the intestine

The inflammatory stimulus and shock can cause microvascular

damage and ischaemia to the gut mucosa. This reduces gut motility and can prevent the absorption of food. Failure of enteral feeding in a patient with a large burn is a life-threatening complication. This process also increases the translocation of gut bacteria, which can become an important source of infection in large burns. Gut mucosal swelling, gastric stasis and peritoneal oedema can also cause abdominal compartment syndrome, which splints the diaphragm and increases the airway pressures needed for respiration.

Danger to peripheral circulation

In full-thickness burns, the collagen fibres are coagulated. The normal elasticity of the skin is lost. A circumferential full-thickness burn to a limb acts as a tourniquet as the limb swells. If untreated, this will progress to limb-threatening ischaemia (Summary box 30.5).

Summary box 30.5

Other complications of burns

- Infection from the burn site, lungs, gut, lines and catheters
- Malabsorption from the gut
- Circumferential burns may compromise circulation to a limb

IMMEDIATE CARE OF THE BURN PATIENT

Pre-hospital care

The principles of pre-hospital care are:

- **Ensure rescuer safety.** This is particularly important in house fires and in the case of electrical and chemical injuries.
- **Stop the burning process.** Stop, drop and roll is a good method of extinguishing fire burning on a person.
- **Check for other injuries.** A standard ABC (airway, breathing, circulation) check followed by a rapid secondary survey will ensure that no other significant injuries are missed. Patients burned in explosions or even escaping from fires may have head or spine injuries and other life-threatening problems.
- **Cool the burn wound.** This provides analgesia and slows the delayed microvascular damage that can occur after a burn injury. Cooling should occur for a minimum of 10 minutes and is effective up to 1 hour after the burn injury. It is a particularly important first aid step in partial-thickness burns, especially scalds. In temperate climates, cooling should be at about 15°C, and hypothermia must be avoided.
- **Give oxygen.** Anyone involved in a fire in an enclosed space should receive oxygen, especially if there is an altered consciousness level.
- **Elevate.** Sitting a patient up with a burned airway may prove life-saving in the event of a delay in transfer to hospital care. Elevation of burned limbs will reduce swelling and discomfort.

Hospital care

The principles of managing an acute burn injury are the same as in any acute trauma case:

- A, Airway control
- B, Breathing and ventilation
- C, Circulation
- D, Disability – neurological status
- E, Exposure with environmental control
- F, Fluid resuscitation.

The possibility of injury additional to the burn must be sought both clinically and from the history, and treated appropriately. The major determinants of severity of any burn injury are the percentage of TBSA that is burned, the presence of an inhalation injury and the depth of the burn (Summary box 30.6).

Not all burned patients will need to be admitted to a burns unit, but the main criteria are given in Table 30.1.

Summary box 30.6

Major determinants of the outcome of a burn

- Percentage surface area involved
- Depth of burns
- Presence of an inhalational injury

Airway

The burned airway creates problems for the patient by swelling and, if not managed proactively, can completely occlude the upper airway. The treatment is to secure the airway with an endotracheal tube until the swelling has subsided, which is usually after about 48 hours. The symptoms of laryngeal oedema, such as change in voice, stridor, anxiety and respiratory difficulty, are very late symptoms. Intubation at this point is often difficult or impossible owing to swelling, so acute cricothyroidotomy equipment must be at hand when intubating patients with a delayed diagnosis of airway burn. Because of this, early intubation of suspected airway burn is the treatment of choice in such patients. The time-frame from burn to airway occlusion is usually between 4 and 24 hours, so there is time to make a sensible decision with senior staff and allow an experienced anaesthetist to intubate the patient (Summary box 30.7).

Summary box 30.7

Initial management of the burned airway

- Early elective intubation is safest
- Delay can make intubation very difficult because of swelling
- Be ready to perform an emergency cricothyroidotomy, if intubation is delayed

The key in the management of airway burn is the history and early signs, rather than the symptoms. The history is of inhalation of hot gases such as in a house or car fire. Clues on examination include blisters on the hard palate, burned nasal mucosa and loss of all the hair in the nose (the anterior hairs are often burned), but perhaps the most valuable signs are the presence of deep burns around the mouth and in the neck (Summary box 30.8).

Table 30.1 The criteria for acute admission to a burns unit.

Suspected airway or inhalational injury
Any burn likely to require fluid resuscitation
Any burn likely to require surgery
Patients with burns of any significance to the hands, face, feet or perineum
Patients whose psychiatric or social background makes it inadvisable to send them home
Any suspicion of non-accidental injury
Any burn in a patient at the extremes of age
Any burn with associated potentially serious sequelae, including high-tension electrical burns and concentrated hydrofluoric acid burns

Summary box 30.8

Recognition of the potentially burned airway

- A history of being trapped in the presence of smoke or hot gases
- Burns on the palate or nasal mucosa, or loss of all the hairs in the nose
- Deep burns around the mouth and neck

Breathing

Inhalational injury

Time is also a factor; anyone trapped in a fire for more than a couple of minutes must be observed for signs of smoke inhalation. Other signs that raise suspicion are the presence of soot in the nose and the oropharynx and a chest radiograph showing patchy consolidation.

The clinical features are a progressive increase in respiratory effort and rate, rising pulse, anxiety and confusion and decreasing oxygen saturation. These symptoms may not be apparent immediately and can take 24 hours to 5 days to develop.

Treatment starts as soon as this injury is suspected and the airway is secure. Physiotherapy, nebulisers and warm humidified oxygen are all useful. The patient's progress should be monitored using respiratory rate, together with blood gas measurements. If the situation deteriorates, continuous or intermittent positive pressure may be used with a mask or T-piece. In the severest cases, intubation and management in an intensive care unit will be needed.

The key, therefore, in the management of inhalational injury is to suspect it from the history, institute early management and observe carefully for deterioration.

Thermal burn injury to the lower airway

These rare injuries can occur with steam injuries. Their management is supportive and the same as that for an inhalational injury.

Metabolic poisoning

Any history of a fire within an enclosed space and any history of altered consciousness are important clues to metabolic poisoning. Blood gases must be measured immediately if poisoning is a possibility. Carboxyhaemoglobin levels raised above 10 per

cent must be treated with high inspired oxygen for 24 hours to speed its displacement from haemoglobin. Metabolic acidosis is a feature of this and other forms of poisoning.

Once again, the key to diagnosing these injuries is suspicion from the history. Blood gas measurement will confirm the diagnosis. The treatment is oxygen.

Mechanical block to breathing

Any mechanical block to breathing from the eschar of a significant full-thickness burn on the chest wall is obvious from the examination. There will also be carbon dioxide retention and high inspiratory pressures if the patient is ventilated. The treatment is to make some scoring cuts through the burned skin to allow the chest to expand (escharotomy). The nerves have been destroyed in the skin, and this procedure is not painful for the patient.

ASSESSMENT OF THE BURN WOUND

Assessing size

Burn size needs to be formally assessed in a controlled environment. This allows the area to be exposed and any soot or debris washed off. Care should be taken not to cause hypothermia during this stage. In the case of smaller burns or patches of burn, the best measurement is to cut a piece of clean paper the size of the patient's whole hand (digits and palm), which represents 1 per cent TBSA, and match this to the area. Another accurate way of measuring the size of burns is to draw the burn on a Lund and Browder chart (Figure 30.3), which maps out the percentage TBSA of sections of our anatomy. It also takes into account different proportional body surface area in children according to age. The rule of nines, which states that each upper limb is 9 per cent TBSA, each lower limb 18 per cent, the torso 18 per cent each side and the head and neck 9 per cent, can be used as a rough guide to TBSA outside the hospital environment (Summary box 30.9).

Summary box 30.9

Assessing the area of a burn

- The patient's whole hand is 1 per cent TBSA, and is a useful guide in small burns
- The Lund and Browder chart is useful in larger burns
- The rule of nines is adequate for a first approximation only

Assessing depth from the history

The first indication of burn depth comes from the history (Table 30.2). The burning of human skin is temperature- and time-dependent. It takes 6 hours for skin maintained at 44°C to suffer irreversible changes, but a surface temperature of 70°C for 1 s is all that is needed to produce epidermal destruction. Taking an example of hot water at 65°C: exposure for 45 s will produce a full-thickness burn, for 15 s a deep partial-thickness burn and for 7 s a superficial partial-thickness burn (Summary box 31.10).

Figure 30.3 The Lund and Browder chart.

Table 30.2 Causes of burns and their likely depth.

Cause of burn	Probable depth of burn
Scald	Superficial, but with deep dermal patches in the absence of good first aid. Will be deep in a young infant
Fat burns	Deep dermal
Flame burns	Mixed deep dermal and full thickness
Alkali burns, including cement	Often deep dermal or full thickness
Acid burns	Weak concentrations superficial; strong concentrations deep dermal
Electrical contact burn	Full thickness

Summary box 30.10

Assessing the depth of a burn

- The history is important – temperature, time and burning material
- Superficial burns have capillary filling
- Deep partial-thickness burns do not blanch, but have some sensation
- Full-thickness burns feel leathery and have no sensation

Superficial partial-thickness burns

The damage in these burns goes no deeper than the papillary dermis. The clinical features are blistering and/or loss of the epidermis. The underlying dermis is pink and moist. The capillary return is clearly visible when blanched. There is little or no fixed capillary staining. Pinprick sensation is normal. Superficial partial-thickness burns heal without residual scarring in 2 weeks. The treatment is non-surgical (Figure 30.4).

Deep partial-thickness burn

These burns involve damage to the deeper parts of the reticular dermis (Figure 30.5). Clinically, the epidermis is usually lost. The exposed dermis is not as moist as that in a superficial burn. There is often abundant fixed capillary staining, especially if examined after 48 hours. The colour does not blanch with pressure under the examiner's finger. Sensation is reduced, and the patient is unable to distinguish sharp from blunt pressure when examined with a needle. Deep dermal burns take 3 or more weeks to heal without surgery and usually lead to hypertrophic scarring (Figure 30.6).

Full-thickness burns

The whole of the dermis is destroyed in these burns (Figure 30.7). Clinically, they have a hard, leathery feel. The appearance can vary from that similar to the patient's normal skin to charred black, depending upon the intensity of the heat. There is no capillary return. Often, thrombosed vessels can be seen under the skin. These burns are completely anaesthetised: a needle can be stuck deep into the dermis without any pain or bleeding.

FLUID RESUSCITATION

The principle of fluid resuscitation is that the intravascular volume must be maintained following a burn in order to provide sufficient circulation to perfuse not only the essential visceral organs such as the brain, kidneys and gut, but also the peripheral tissues, especially the damaged skin (Summary box 30.11).

Intravenous resuscitation is appropriate for any child with a burn greater than 10 per cent TBSA. The figure is 15 per cent TBSA for adults. In some parts of the world, intravenous resuscitation is commenced only with burns that approach 30 per cent TBSA. If oral resuscitation is to be commenced, it is important that the water given is not salt free. It is rarely possible to undergo significant diuresis in the first 24 hours in view of the stress hormones that are present. Hyponatraemia and water intoxication can be fatal. It is therefore appropriate to give oral rehydration with a solution such as Dioralyte®.

The resuscitation volume is relatively constant in proportion to the area of the body burned and, therefore, there are formulae that calculate the approximate volume of fluid needed for the

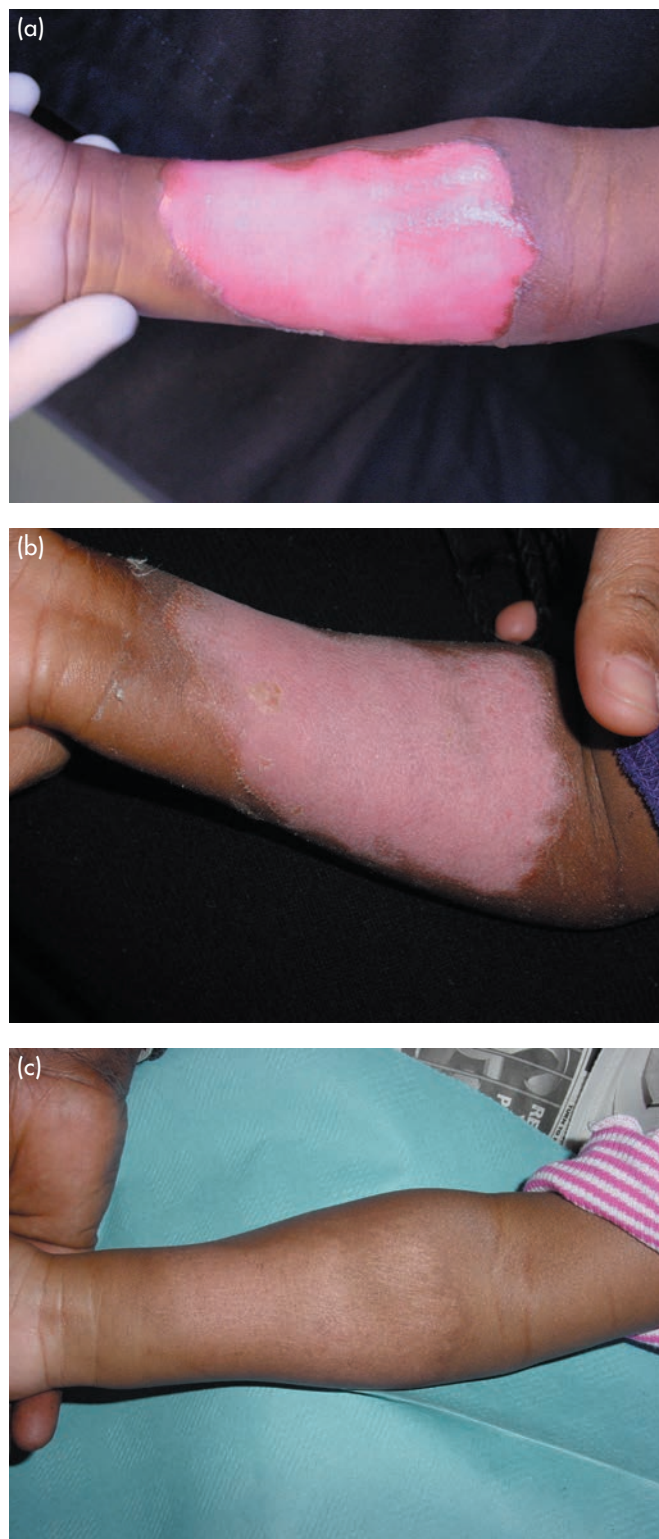

Figure 30.4 (a) A superficial partial-thickness scald 24 hours after injury. The dermis is pink and blanches to pressure. (b) At 2 weeks, the wound is healed but lacks pigment. (c) At three months, the pigment is returning.

Summary box 30.11

Fluids for resuscitation

- In children with burns over 10 per cent TBSA and adults with burns over 15 per cent TBSA, consider the need for intravenous fluid resuscitation
- If oral fluids are to be used, salt must be added
- Fluids needed can be calculated from a standard formula
- The key is to monitor urine output

Figure 30.5 (a) A deep dermal burn undergoing tangential shaving. The dead dermis is removed layer by layer until healthy bleeding is seen. The burn is pale because it was dressed with silver sulphadiazine cream, but no blanching was visible under this layer. The patient was unable to differentiate between pressure from the sharp and blunt ends of a needle. (b) A thin, split-thickness graft harvested from the thigh. (c) The thin graft is placed in the dermal remnants. The rete pegs can be seen between the remnants of the dermis through the graft.

Figure 30.6 Hypertrophic scarring following a deep dermal burn.

Figure 30.7 (a) A full-thickness burn on admission just prior to escharotomy. The wound is wrapped in cling film while in transit. The patient's facial burn is shown in Figure 30.10. (b) Excision of the same full-thickness burn, down to healthy fat.

resuscitation of a patient of a given body weight with a given percentage of the body burned. These regimens follow the fluid loss, which is at its maximum in the first 8 hours and slows, such that, by 24–36 hours, the patient can be maintained on his or her normal daily requirements.

There are three types of fluid used. The most common is Ringer's lactate or Hartmann's solution; some centres use human albumin solution or fresh-frozen plasma, and some centres use hypertonic saline.

Perhaps the simplest and most widely used formula is the Parkland formula. This calculates the fluid to be replaced in the first 24 hours by the following formula: total percentage body surface area \times weight (kg) \times 4 = volume (mL). Half this volume is given in the first 8 hours and the second half is given in the subsequent 16 hours.

Crystalloid resuscitation

Ringer's lactate is the most commonly used crystalloid. Crystalloids are said to be as effective as colloids for maintaining intravascular volume. They are also significantly less expensive. Another reason for the use of crystalloids is that even large protein molecules leak out of capillaries following burn injury; however, non-burnt capillaries continue to sieve proteins virtually normally.

In children, maintenance fluid must also be given. This is normally dextrose–saline given as follows:

- 100 mL/kg for 24 hours for the first 10 kg;
- 50 mL/kg for the next 10 kg;
- 20 mL/kg for 24 hours for each kilogram over 20 kg body weight.

Hypertonic saline

Human albumin solution (HAS) is a commonly used colloid.

Hypertonic saline has been effective in treating burns shock for many years. It produces hyperosmolarity and hypernatraemia. This reduces the shift of intracellular water to the extracellular space. Advantages include less tissue oedema and a resultant decrease in escharotomies and intubations.

Colloid resuscitation

Plasma proteins are responsible for the inward oncotic pressure that counteracts the outward capillary hydrostatic pressure. Without proteins, plasma volumes would not be maintained as there would be oedema. Proteins should be given after the first 12 hours of burn because, before this time, the massive fluid shifts cause proteins to leak out of the cells.

The most common colloid-based formula is the Muir and Barclay formula:

- $0.5 \times$ percentage body surface area burnt \times weight = one portion;
- periods of 4/4/4, 6/6 and 12 hours, respectively;
- one portion to be given in each period.

Monitoring of resuscitation

The key to monitoring of resuscitation is urine output. Urine output should be between 0.5 and 1.0 mL/kg body weight per hour. If the urine output is below this, the infusion rate should be increased by 50 per cent. If the urine output is inadequate and the patient is showing signs of hypoperfusion (restlessness with

tachycardia, cool peripheries and a high haematocrit), then a bolus of 10 mL/kg body weight should be given. It is important that patients are not overresuscitated, and urine output in excess of 2 mL/kg body weight per hour should signal a decrease in the rate of infusion.

Other measures of tissue perfusion such as acid–base balance are appropriate in larger, more complex burns, and a haematocrit measurement is a useful tool in confirming suspected under- or overhydration. Those with cardiac dysfunction, acute or chronic, may well need more exact measurement of filling pressure, preferably by transoesophageal ultrasound or with the more invasive central line.

TREATING THE BURN WOUND

Escharotomy

Circumferential full-thickness burns to the limbs require emergency surgery (Figure 30.8). The tourniquet effect of this injury is easily treated by incising the whole length of full-thickness burns. This should be done in the mid-axial line, avoiding major nerves (Table 30.3). One should remember that an escharotomy can cause a large amount of blood loss; therefore, adequate blood should be available for transfusion if required.

Thereafter, the management of the burn wound remains the same, irrespective of the size of the injury. The burn needs to be cleaned, and the size and depth need to be assessed. Full thickness burns and deep partial-thickness burns that will require operative treatment will need to be dressed with an antibacterial dressing to delay the onset of colonisation of the wound.

Full-thickness burns and obvious deep dermal wounds

The four most common dressings for full-thickness and contaminated wounds are listed in Table 30.4.

Dressings with nanocrystalline silver

- **Silver sulphadiazine cream (1 per cent).** This gives broad-spectrum prophylaxis against bacterial colonisation and is particularly effective against *Pseudomonas aeruginosa* and also methicillin-resistant *Staphylococcus aureus*.

Figure 30.8 A full-thickness burn to the upper limb with a mid-axial escharotomy. The soot and debris have been washed off.

Table 30.3 Key features of escharotomy placement.

Upper limb	Mid-axial, anterior to the elbow medially to avoid the ulnar nerve
Hand	Midline in the digits. Release muscle compartments if tight. Best done in theatre and with an experienced surgeon
Lower limb	Mid-axial. Posterior to the ankle medially to avoid the saphenous vein
Chest	Down the chest lateral to the nipples, across the chest below the clavicle and across the chest at the level of the xiphisternum
General rules	Extend the wound beyond the deep burn Diathermy any significant bleeding vessels Apply haemostatic dressing and elevate the limb postoperatively

Table 30.4 Options for topical treatment of deep burns.

1% silver sulphadiazine cream
0.5% silver nitrate solution
Mafenide acetate cream
Serum nitrate, silver sulphadiazine and cerium nitrate

- **Silver nitrate solution (0.5 per cent).** Again, this is highly effective as a prophylaxis against *Pseudomonas* colonisation, but it is not as active as silver sulphadiazine cream against some of the Gram-negative aerobes. The other disadvantage of this solution is that it needs to be changed or the wounds resoaked every 2–4 hours. It also produces black staining of all the furniture surrounding the patient.
- **Mafenide acetate cream.** This is popular, especially in the United States, but is painful to apply. It is usually used as a 5 per cent topical solution, but has been associated with metabolic acidosis.
- **Silver sulphadiazine and cerium nitrate.** This is also a very useful burn dressing, especially for full-thickness burns. It induces a hard effect on the burned skin and has been shown in certain instances, especially in elderly patients, to reduce some of the cell-mediated immunosuppression that occurs in burns. Cerium nitrate forms a sterile eschar and is specially useful in treating burns when a conservative treatment option has been chosen. Cerium nitrate has also been shown to boost cell-mediated immunity in these patients.

Superficial partial-thickness wounds and mixed-depth wounds

Around the world, a wide variety of substances are used to treat these wounds, from honey or boiled potato peel to synthetic biological dressings with live cultured fibroblasts within the matrix. This is testament to the fact that superficial partial-thickness burns will heal almost irrespective of the dressing. Thus, the key lies with dressings that are easy to apply, non-painful, reduce pain, simple to manage and locally available. The choice of dressings does, however, become crucial in the case of burns that border on being deep dermal (Figure 30.9). Here, the choice of

dressing can make the difference between scar and no scar and/or operation and no operation. Some of the options for dressing choice are described below.

If the wound is heavily contaminated as a result of the accident, then it is prudent to clean the wound formally under a general anaesthetic. With more chronic contamination, silver sulphadiazine cream dressing for 2 or 3 days is very effective and can be changed to a dressing that is more efficient at promoting healing after this period.

The simplest method of treating a superficial wound is by exposure. The initial exudate needs to be managed by frequent changes of clean linen around the patient but, after a few days, a dry eschar forms, which then separates as the wound epithelialises. This is often used in hot climates and for small burns on the face. However, this method is painful and requires an intensive amount of nursing support. A variation on this theme is to cover

Figure 30.9 (a) A scald to the chest from boiling water, mainly superficial but in some areas close to being deep dermal. This was treated with a hydrocolloid dressing. (b) There are two tiny areas of hyperthrophy indicating how close the burn was to being deep dermal. The good first aid this patient received probably made a difference to the outcome.

the wound with a permeable wound dressing, such as Mefix® or Fixamol®. This allows the wounds to dry but, because it is a covering, it avoids the problems of the wound adhering to the sheets and clothes. A similar method of managing these types of burn is to place a Vaseline-impregnated gauze (with or without an antiseptic, such as chlorhexidine) over the wound. An alternative is a fenestrated silicone sheet (e.g. Mepitel®). These can then be backed with swabs to absorb the exudate. The Vaseline gauze or silicone layer is used to prevent the swabs adhering to the wound and reduces the stiffness of the dry eschar, preventing it from cracking so easily. The swabs need to be changed after the first 48 hours as they are often soaked. After that, they can be left for longer.

More interactive dressings include hydrocolloids and biological dressings. Hydrocolloid dressings need to be changed every 3–5 days. They are particularly useful in mixed-depth burns as the high protease levels under the occlusive dressings aid with the debridement of the deeper areas of burn. They also provide a moist environment, which is good for epithelialisation. Duoderm® is a hydrocolloid dressing. There is good evidence for its value in burns.

Biological, synthetic (e.g. Biobrane®) and natural (e.g. amniotic membranes) dressings also provide good healing environments and do not need to be changed. They are ideal for one-stop management of superficial burns, being easy to apply and comfortable. However, they will become detached if applied to deep dermal wounds as the eschar needs to separate. They are therefore not as useful in mixed-depth wounds (Summary box 30.12).

Early debridement and grafting is the key to effectively treating deep partial- and full-thickness burns in a majority of cases.

Summary box 30.12

Principles of dressings for burns

- Full-thickness and deep dermal burns need antibacterial dressings to delay colonisation prior to surgery
- Superficial burns will heal and need simple dressings
- An optimal healing environment can make a difference to outcome in borderline depth burns

ADDITIONAL ASPECTS OF TREATING THE BURNED PATIENT

Analgesia

Acute

Analgesia is a vital part of burns management. Small burns, especially superficial burns, respond well to simple oral analgesia, paracetamol and non-steroidal anti-inflammatory drugs. Topical cooling is especially soothing. Large burns require intravenous opiates. Intramuscular injections should not be given in acute burns over 10 per cent of TBSA, as absorption is unpredictable and dangerous.

Subacute

In patients with large burns, continuous analgesia is required, beginning with infusions and continuing with oral tablets,

such as slow-release morphine. Powerful, short-acting analgesia should be administered before dressing changes. Administration may require an anaesthetist, as in the case of general anaesthesia or midazolam and ketamine, or less intensive supervision, as in the case of morphine and nitrous oxide.

Energy balance and nutrition

One of the most important aspects in treating burns patients is nutrition. Any adult with a burn greater than 15 per cent (10 per cent in children) of TBSA has an increased nutritional requirement. All patients with burns of 20 per cent of TBSA or greater should receive a nasogastric tube. (Feeding should start within 6 hours of the injury to reduce gut mucosal damage.) A number of different formulae are available to calculate the energy requirements of patients (Summary box 30.13).

Summary box 30.13

Nutrition in burns patients

- Burns patients need extra feeding
- A nasogastric tube should be used in all patients with burns over 15 per cent of TBSA
- Removing the burn and achieving healing stops the catabolic drive

Burn injuries are catabolic in the acute episode. Successful management of the patient's energy balance involves a number of strategies. The catabolic drive continues while the wound remains unhealed and, therefore, rapid excision of the burn and stable coverage of the wound are the most significant factors in reversing this. Obligatory energy utilisation must be reduced to a minimum by keeping the patient warm with good environmental control. The excess energy requirements must be provided for and the nutritional balance monitored by measuring weight and nitrogen balance (see Table 30.5).

Monitoring and control of infection

Patients with major burns are immunocompromised, having large portals of entry to pathogenic and opportunistic bacteria and fungi via the burn wound (Summary box 30.14). They have compromised local defences in the lungs and gut due to oedema, and usually have monitoring lines and catheters, which themselves represent portals for infection.

Table 30.5 Commonly used feeding formulae.

Curreri formula	Age 16–59 years: (25)VV + (40)TBSA Age 60+ years: (20)VV + (65)TBSA
Sutherland formula	Children: 60 kcal/kg + 35 kcal%TBSA Adults: 20 kcal/kg + 70 kcal%TBSA
Protein needs	Greatest nitrogen losses between days 5 and 10 20% of kilocalories should be provided by proteins
Davies formula	Children: 3 g/kg + 1 g%TBSA Adults: 1 g/kg + 3 g%TBSA

TBSA, total body surface area.

Summary box 30.14**Infection control in burns patients**

- Burns patients are immunocompromised
- They are susceptible to infection from many routes
- Sterile precautions must be rigorous
- Swabs should be taken regularly
- A rise in white blood cell count, thrombocytosis and increased catabolism are warnings of infection

Control of infection begins with policies on hand-washing and other cross-contamination prevention measures. Bacteriological surveillance of the wound, catheter tips and sputum helps to build a picture of the patient's flora. If there are signs of infection, then further cultures need to be taken and antibiotics started. This is often initially on a best guess basis, hence the usefulness of prior surveillance; close liaison with a bacteriologist is essential. In patients with large burns that remain catabolic, the core temperature is usually reset by the hypothalamus above 37°C. Significant temperatures are those above 38.5°C, but often other signs of infection are more useful to the clinician. These include significant rise or fall in the white cell count, thrombocytosis, increasing signs of catabolism and decreasing clinical status of the patient.

Nursing care

Burns patients require particularly intensive nursing care. Nurses are the primary effectors of many decisions that directly affect healing. Bandaged hands and joints which are stiff and painful need careful coaxing. Personal hygiene, baths and showers all become time-consuming and painful, but are vital parts of the patient's physiotherapy. Their success or failure has a powerful psychological impact on the patient and his or her family.

Physiotherapy

All burns cause swelling, especially burns to the hands. Elevation, splintage and exercise reduce swelling and improve the final outcome. The physiotherapy needs to be started on day 1, so that the message can be reinforced on a daily basis.

Psychological

A major burn is an overwhelming event, outside the normal experience, which overwhelms the patient's coping ability, suspends the patient's sense of safety and causes post-traumatic reactions. These are normal and usually self-limiting, receding as the patient heals. The features of this intensity of experience are of intrusive reactions, arousal reactions and avoidance reactions.

SURGERY FOR THE ACUTE BURN WOUND

Any deep partial-thickness and full-thickness burns, except those that are less than about 4 cm², need surgery. Any burn of indeterminate depth should be reassessed after 48 hours. This is because burns that initially appear superficial may well deepen over that time. Delayed microvascular injury is especially common in scalds (Summary box 30.15).

Summary box 30.15**Surgical treatment of deep burns**

- Deep dermal burns need tangential shaving and split-skin grafting
- All but the smallest full-thickness burns need surgery
- The anaesthetist needs to be ready for significant blood loss
- Topical adrenaline reduces bleeding
- All burnt tissue needs to be excised
- Stable cover, permanent or temporary, should be applied at once to reduce burn load

The essence of burns surgery is control. First and foremost, the anaesthetist needs good control of the patient. A wide-bore cannula should be used and the patient's blood pressure must be monitored adequately. If a large excision is considered, then an arterial line (to monitor blood pressure) and a central venous pressure monitor are needed. The anaesthetist also needs measurements and control of the acid-base balance, clotting time and haemoglobin levels. The core temperature of the patient must not drop below 36°C, otherwise clotting irregularities will be compounded.

For most burn excisions, subcutaneous injection of a dilute solution of adrenaline 1:1 000 000 or 1:500 000 and tourniquet control are important for controlling blood loss.

In deep dermal burns, the top layer of dead dermis is shaved off until punctate bleeding is observed and the dermis can be seen to be free of any small thrombosed vessels (Figure 30.5a). A topical solution of 1:500 000 adrenaline also helps to reduce bleeding, as does the application of the skin graft. The use of a tourniquet during burn excisions in the limbs helps to decrease blood loss and maintain control.

Full-thickness burns require full-thickness excision of the skin (Figure 30.5b). In certain circumstances, it is appropriate to go down to the fascia but, in most cases, the burn excision is down to viable fat. Wherever possible, a skin graft should be applied immediately. With very large burns, the use of synthetic dermis or homografts provides temporary stable coverage and will allow complete excision of the wound and thus reduce the burn load on the patient.

Postoperative management of these patients obviously requires careful evaluation of fluid balance and levels of haemoglobin. The outer dressings will quickly be soaked through with serum and will need to be changed on a regular basis to reduce the bacterial load within the dressing.

Physiotherapy and splints are important in maintaining range of movement and reducing joint contracture. Elevation of the appropriate limbs is important. The hand must be splinted in a position of function after grafting, although the graft needs to

The Guinea Pig Club. Sir Archibald McIndoe (1900–1960), born in New Zealand, was appointed in 1938 as consultant plastic surgeon to the Royal Air Force. He trained with his cousin, Sir Harold Gillies, another internationally reputed plastic surgeon. McIndoe became world famous for his pioneering work on Battle of Britain pilots who were badly burnt. His work on these airmen, who needed several operations, and using his innovative technical and psychological methods, was the start of a life-long service. The young fighter pilots were therefore referred to as 'guinea pigs' – thus was formed The Guinea Pig Club. McIndoe referred to his patients as 'the boys' who in turn called him 'the boss' or 'the maestro'. To this day, some of the members of the Guinea Pig Club from all over the world still meet on an annual basis in Sussex. McIndoe founded the British Association of Plastic Surgeons (BAPS).

be applied in the position of maximal stretch. Knees are best splinted in extension, axillae in abduction. Supervised movement by the physiotherapists, usually under direct vision of any affected joints, should begin after about 5 days.

Delayed reconstruction and scar management

Delayed reconstruction of burn injuries is common for large full-thickness burns. In the early healing period, acute contractures around the eye need particular attention. Eyelids must be grafted at the first sign of difficulty in closing the eyelids, and this must be done before the patient has any symptoms of exposure keratitis (Figure 30.10). Other areas that require early intervention are any contracture causing significant loss of range of movement of a joint. This is particularly important in the hand and axilla (Summary box 30.16).

Summary box 30.16

Delayed reconstruction of burns

- Eyelids must be treated before exposure keratitis arises
- Transposition flaps and Z-plasties with or without tissue expansion are useful
- Full-thickness grafts and free flaps may be needed for large or difficult areas
- Hypertrophy is treated with pressure garments
- Pharmacological treatment of itch is important

An established contracture can be treated in a number of ways. Burn alopecia is best treated with tissue expansion of the unburned hair-bearing skin. Tissue expansion is also a useful technique for isolated burns and other areas with adjacent normal skin. Z-plasty is useful in the situation in which there is a single band and a transposition flap is useful in wider bands of scarring (Figure 30.11). In areas of circumferential or very broad areas of scarring, the only real treatment is incision and replacement with tissue. By far the best tissue for replacement is from either a full-thickness graft or vascularised tissue as in a free flap. Occasionally, the situation requires the less ideal covering of split skin, possibly with an artificial dermis, such as Integra® (Figure 30.12). These last two options require prolonged scar management after their use.

Hypertrophy of many scars will respond to pressure garments. These need to be worn for a period of 6–18 months. Where it is difficult to apply pressure with pressure garments, or with smaller areas of hypertrophy, silicone patches will speed scar maturation, as will intralesional injection of steroid. Itching and dermatitis in burn scar areas are common. Pharmacological treatment of itch is an essential adjunct to therapy.

MINOR BURNS/OUTPATIENT BURNS

Local burn wound care

Blisters

Whether to remove blisters or leave them intact has been the subject of much debate. Proponents of blister removal quote laboratory studies which show that blister fluid depresses immune function, slowing down chemotaxis and intracellular killing and also acting as a medium for bacterial growth.

Conversely, other authors advocate leaving blisters intact as they form a sterile stratum spongiosum. Leaving a ruptured blister is not advised.

Initial cleaning of the burn wound

Washing the burn wound with chlorhexidine solution is ideal for this purpose.

Topical agents

For initial management of minor burns that are superficial or partial thickness, dressings with a non-adherent material, such as Vaseline-impregnated gauze or Mepitel are often sufficient. These dressings are left in place for 5 days. These burns, by definition, should be healed after 7–10 days. Various topical creams and ointments have been used for the treatment of minor burns. All published comparative data show no advantage of these agents over petroleum gauze.

Silver sulphadiazine (1 per cent) or Flamazine® is the most commonly used topical agent. However, it should be avoided in pregnant women, nursing mothers and infants less than two months of age because of the increased possibility of kernicterus in these patients.

Dressing the minor burn wound

The aims of dressing are to decrease wound pain and to protect and isolate the burn wound. The small superficial burn requires Vaseline gauze or another non-adherent dressing, such as Mepitel, as the first layer. Following this, gauze or Kerlix® is wrapped around with sufficient tightness to keep the dressing intact, but not to impede the circulation. This is further wrapped with bandage. It is important to realise that bulkiness of dressings in the minor burn wound depends upon the amount of wound discharge. A special case is burns of the hands where dressings should be minimised so as not to impede mobilisation and physiotherapy.

Synthetic burn wound dressings are popular as they:

- decrease pain associated with dressings;
- improve healing times;
- decrease outpatient appointments;
- lower overall costs.

Biobrane is a bilaminar dressing made up of an inner layer of knitted nylon threads coated with porcine collagen and an outer layer of rubberised silicone impervious to gases, but not to fluids and bacteria. Wounds to be dressed with Biobrane should be carefully selected. Burn wounds should be fresh (less than 24 hours), sensate, show capillary blanching and refill. Biobrane® should be applied to the wound after removal of all blisters. It should be checked at 48 hours for adherence and any signs of infection. It should be removed if any sign of infection is found.

Duoderm or hydrocolloid dressings are not bulky, help in healing and can be kept in place for 48–72 hours. They provide a moist environment, which helps in re-epithelialisation of the burn wound.

Healing of burn wounds

Burns that are being managed conservatively should be healed within 3 weeks. If there are no signs of re-epithelialisation in this time, the wound requires debridement and grafting.

Figure 30.10 (a) A mixed superficial and deep burn to the face after a petrol explosion. The patient's airway was protected prior to transfer. He has an orogastric tube and feeding has commenced. (b) The face dressed with a hydrocolloid dressing. The endotracheal tube is wired to the teeth. (c) Day 6, the swelling is still present. (d) Six weeks after injury. With the mouth wide open, the lower eyelids are pulled down, demonstrating the intrinsic and extrinsic shortening of the eyelids. (e) Three months after injury. The eyelids have been grafted but note the contracture of the lips. (f) Six months after injury. The patient has had grafts to the upper and lower lips.

Figure 30.11 A transposition flap bringing normal skin across a scarred elbow.

Infection

Infection in the minor burn should be tackled very aggressively as it is known to convert a superficial burn to a partial-thickness burn and a partial- to a deep partial-thickness burn, respectively. It should be managed using a combination of topical and systemic agents. Debridement and skin grafting should also be considered.

Itching

Most burn patients have itchy wounds. Histamine and various endopeptides are said to be the causative factors of itching. Antihistamines, analgesics, moisturising creams, aloe vera and antibiotics have all been tried with varying degrees of success.

Traumatic blisters

The healed burn wound is prone to getting traumatic blisters because the new epithelium is very fragile. Non-adherent dressings usually suffice; regular moisturisation is also useful in this condition.

Figure 30.12 (a) A healed full-thickness leg burn prior to resurfacing with Integra. (b) The burn scar has been excised and Integra applied prior to split-thickness skin grafting. (c) Six months after Integra resurfacing. The skin is smoother and more supple, and the scar has faded.

NON-THERMAL BURN INJURY

Electrical injuries

Electrical injuries are usually divided into low- and high-voltage injuries, the threshold being 1000 V (Summary box 30.17).

Summary box 30.17

Electrical burns

- Low-voltage injuries cause small, localised, deep burns
- They can cause cardiac arrest through pacing interruption without significant direct myocardial damage
- High-voltage injuries damage by flash (external burn) and conduction (internal burn)
- Myocardium may be directly damaged without pacing interruption
- Limbs may need fasciotomies or amputation
- Look for and treat acidosis and myoglobinuria

Low-tension injuries

Low-tension or domestic appliance injuries do not have enough energy to cause destruction to significant amounts of subcutaneous tissues when the current passes through the body. The resistance is too great. The entry and exit points, normally in the fingers, suffer small deep burns; these may cause underlying tendon and nerve damage, but there will be little damage between. The alternating current creates a tetany within the muscles, and thus patients often describe how they were unable to release the device until the power was turned off. The main danger with these injuries is from the alternating current interfering with normal cardiac pacing. This can cause cardiac arrest. The electricity itself does not usually cause significant underlying myocardial damage, so resuscitation, if successful, should be lasting.

High-tension injuries

High-tension electrical injuries can be caused by one of three sources of damage: the flash, the flame and the current itself.

When a high-tension line is earthed, enormous energy is released as the current travels from the line to the earth. It can arc over the patient, causing a flash burn. The extremely rapid heating of the air causes an explosion that often propels the victim backwards. The key here is that the current travelled from the line to the earth directly and not through the patient. The flash, however, can go on to ignite the patient's clothes and so cause a normal flame burn.

In accidents with overhead lines, the patient often acts as the conduction rod to earth. In these injuries, there is enough current to cause damage to the subcutaneous tissues and muscles. The entry and exit points are damaged but, importantly, the current can cause huge amounts of subcutaneous damage between these two points. These can be extremely serious injuries.

The damage to the underlying muscles in the affected limb can cause the rapid onset of compartment syndrome. The release of the myoglobins will cause myoglobinuria and subsequent renal dysfunction. Therefore, during the resuscitation of these patients, efforts must be made to maintain a high urine output of up to 2 mL/kg body weight per hour. Severe acidosis is common in large electrical burns and may require boluses of bicarbonate. These patients are also at risk of myocardial damage as a result

of direct muscle damage rather than by interference with cardiac pacing. This gives rise to significant electrocardiogram changes, with raised cardiac enzymes. If there is significant damage, there is rapid onset of heart failure. In the case of a severe injury through a limb, primary amputation is sometimes the most effective management (Figure 30.13).

Chemical injuries

There are over 70 000 different chemicals in regular use within industry. Occasionally, these cause burns. Ultimately, there are two aspects to a chemical injury. The first is the physical destruction of the skin and the second is any poisoning caused by systemic absorption (Summary box 30.18).

Summary box 30.18

Chemical burns

- Damage is from corrosion and poisoning
- Copious lavage with water helps in most cases
- Then identify the chemical and assess the risks of absorption

Figure 30.13 (a) An exit wound of a high-tension injury, with a dead big toe and significant damage to the medial portion of the second toe. (b) Amputation and cover with the lateral portion of the second toe.

The initial management of any chemical injury is copious lavage with water. There are only a handful of chemicals for which water is not helpful, for example phosphorus, which is a component of some military devices, and elemental sodium, which is occasionally present in laboratory explosions. These substances need to be physically removed with forceps; however, it is extremely rare that any medical practitioner will encounter these in his or her lifetime. The more common injuries are caused by either acids or alkalis. Alkalis are usually the more destructive and are especially dangerous if they have come into contact with the eyes. After copious lavage, the next step in the management of any chemical injury is to identify the chemical and its concentration and to elucidate whether there is any underlying threat to the patient's life if absorbed systemically.

One acid that is a common cause of acid burns is hydrofluoric acid. Burns affecting the fingers and caused by dilute acid are relatively common. The initial management is with calcium gluconate gel topically; however, severe burns or burns to large areas of the hand can be subsequently treated with Bier's blocks containing calcium gluconate 10 per cent gel. If the patient has been burnt with a concentration greater than 50 per cent, the threat of hypocalcaemia and subsequent arrhythmias then becomes high, and this is an indication for acute early excision. It is best not to split-skin graft these hydrofluoric acid wounds initially, but to do this at a delayed stage.

Ionising radiation injury

These injuries can be divided into groups depending on whether radiation exposure was to the whole body or localised. The management of localised radiation damage is usually conservative until the true extent of the tissue injury is apparent. Should this damage have caused an ulcer, then excision and coverage with vascularised tissue is required.

Whole-body radiation causes a large number of symptoms. The dose of radiation either is or is not lethal. A patient who has suffered whole-body irradiation and is suffering from acute desquamation of the skin has received a lethal dose of radiation, which can cause a particularly slow and unpleasant death. Non-

lethal radiation has a number of systemic effects related to the gut mucosa and immune system dysfunction. Other than giving iodine tablets, the management of these injuries is supportive (Summary box 30.19).

Summary box 30.19

Radiation burns

- Local burns causing ulceration need excision and vascularised flap cover, usually with free flaps
- Systemic overdose needs supportive treatment

Cold injuries

Cold injuries are principally divided into two types: acute cold injuries from industrial accidents and frostbite.

Exposure to liquid nitrogen and other such liquids will cause epidermal and dermal destruction. The tissue is more resistant to cold injury than to heat injury, and the inflammatory reaction is not as marked. The assessment of depth of injury is more difficult, so it is rare to make the decision for surgery early.

Frostbite injuries affect the peripheries in cold climates. The initial treatment is with rapid rewarming in a bath at 42°C. The cold injury produces delayed microvascular damage similar to that of cardiac reperfusion injury. The level of damage is difficult to assess, and surgery usually does not play a role in its management, which is conservative, until there is absolute demarcation of the level of injury.

CHAPTER 31

Plastic and reconstructive surgery

LEARNING OBJECTIVES

To understand:

- The spectrum of plastic surgical techniques used to restore bodily form and function
- The relevant anatomy and physiology of tissues used in reconstruction
- The various skin grafts and how to use them appropriately
- The principles and use of flaps
- How to use plastic surgery to manage difficult and complex tissue loss

HISTORICAL CONTEXT

Reconstructive plastic (from the ancient Greek *plassein*, to mould or shape – also the stem for our modern use of the materials termed ‘plastics’) surgery involves using various techniques to restore form and function to the body when tissues have been damaged by injury, cancer or congenital loss. Its origins can be traced back to ancient Egypt, with wound care depicted in hieroglyphs on papyrus, to India in the sixth century BC, where Sushruta described using the forehead flap to reconstruct a nose, and to Al-Zahrawi, the tenth-century Islamic surgical scholar from Cordoba. Modern techniques were developed after the First World War, especially with Sir Harold Gillies’ work on reconstructing facial injuries (Figure 31.1), which was enabled by new safe anaesthetic intubation (Sir Ivan Magill). Later in the twentieth century, renewed understanding of detailed soft tissue anatomy led to an explosion in the use of new flaps, which with microsurgical methods, craniofacial surgery and tissue expansion resulted in an entirely new set of techniques becoming available to surgeons for reconstructing parts.

Today, the need for reconstructive plastic surgery, especially in developing nations, has never been greater. Road, war and domestic injury inflict life-diminishing effects, which plastic surgery can reduce. The reconstructive surgeon’s ‘toolbox’ is now very diverse and will continue to grow in order to address problem wounds and tissue defects, which arise as modern medical care is more successful in treating cancer, preserving life into old age and salvaging victims of trauma.

Sushruta, regarded as the father of modern surgery, lived in the Indian city of Kashi (now called Banaras) in 600BC (while the exact period is unclear, most scholars maintain that he practised between 600 and 1000BC). A large part of his practice was plastic surgery in the form of rhinoplasty carried out on criminals who had their noses amputated as a punishment for their crimes. His medical pursuits were recorded in ‘*Sushruta Samhita* (compendium)’.

ANATOMY RELATED TO RECONSTRUCTIVE SURGERY

Skin

The surface of the skin is important as a biological layer for homeostasis. Restoring the skin surface is therefore critical even if the underlying structures can await later reconstruction. Epidermis regenerates from deeper follicular elements, with the most superficial layer losing vascularity and acting as a barrier to fluid loss and providing important protection against invasion by microorganisms. (Epidermal keratinocytes can be artificially cultured *in vitro* and are used in some wound management systems.)

The depth of the dermis and the amounts of elastin and skin

Sir Ivan Whiteside Magill, 1888–1986, anaesthetist, Westminster Hospital, London, UK.

Henry Tonks, 1862–1937, commenced a career in surgery, but abandoned it for art and became, from 1917 to 1930, Slade Professor at the Westminster School of Art, London, UK.

adnexal elements, such as sweat glands and hair follicles, vary depending on the functional requirements of the area concerned. This means that some areas are much more vulnerable to injury than others, e.g. the fine flexible elastic skin of the eyelid rapidly suffers a full-thickness burn after a flash burn, whereas thick back skin suffers only a partial loss after the same flash burn.

Skin vascularity is derived from fine perforating vessels that run through underlying muscles or through fascial septal layers, and then horizontally in a subcutaneous plane from which capillaries branch (Figure 31.2). Nerves run axially out from major trunks and are less well defined than most perforating blood vessels.

When local, random-pattern skin flaps are raised, they are lifted at the subcutaneous level and are nourished by the subdermal plexus of blood vessels. However, this plexus can only survive a limited distance from the more substantial arterial branches running in the fascial, septal or muscle-perforating planes. Understanding the anatomy of different parts of the skin and tissues to be moved is a key element of successful plastic surgery.

Without skin, wounds heal by **secondary intention** with fibrosis and contracture (Figure 31.3), and underlying structures are vulnerable to necrosis, chronic infection and dysfunction.

Graft anatomy

Split-thickness skin grafts

Split-thickness skin grafts are harvested by taking all of the

Figure 31.3 A severely contracted hand following burn to the dorsal aspect.

epidermis together with some dermis, leaving the remaining dermis behind to heal the donor site. The thicker the dermis that is taken (seen by more brisk punctate bleeding at the donor site; Figure 31.4), the more durable will be the graft once healed (although it might take longer and require more care), but also the more difficult will be donor site healing (Summary box 31.1).

Figure 31.2 Diagram of skin anatomy with vascular plexus.

Summary box 31.1

Split-thickness skin grafts

- Thicker knife-gap settings give rise to fewer but brisker bleeding points on the donor site.
- Thicker grafts heal with less contracture and are more durable.
- Thinner donor sites heal better.
- Grafts are hairless and do not sweat (these structures are not transferred).

Full-thickness skin grafts

Full-thickness grafts are harvested to incorporate the whole dermis, with the underlying fat trimmed away – unless elements of fat (or even cartilage as well) are deliberately left attached to form a **composite graft**. Full-thickness and composite grafts require the most careful handling and postoperative nursing to help ensure that they ‘take’ in their transplanted site.

How does a skin graft survive?

Split-thickness skin grafts survive initially by **imbibition** of plasma from the wound bed; after 48 hours, fine anastomotic connections are made, which lead to **inosculation** of blood. Capillary ingrowth then completes the healing process with fibroblast maturation. Because only tissues that produce granulation will support a graft, it is usually contraindicated to use grafts to cover exposed tendons, cartilage or cortical bone.

Skin grafts inevitably contract, with the extent of contracture determined by the amount of dermis taken with the graft and the level of postoperative splintage and physiotherapy applied to the grafted site.

CLASSIFICATION

The reconstructive toolbox

Plastic surgery offers a variety of techniques to address clinical problems. Sometimes, a problem is managed using a ‘ladder’ approach, with the simplest methods being used first and only moving to more complex methods when absolutely necessary. However, this is frequently not the ideal approach for best outcomes. If resources permit, it is often more cost-effective and better functionally for the patient to begin with a more complex treatment, with other easier managements held in reserve as ‘lifeboats’. Plastic surgeons now prefer to think of the range of options available as a toolbox from which they can take the most appropriate method to solve a problem, taking into account available skill, resources and the consequences of failure.

The scope of plastic surgery

The tools of reconstruction are used for a wide range of conditions:

- trauma:
 - soft-tissue loss (skin, tendons, nerves, muscle);
 - hand and lower limb injury;
 - faciomaxillary;
 - burns;
- cancer:
 - skin, head and neck, breast, soft tissue sarcoma;
- congenital:

Figure 31.4 Fine punctate bleeding from a split-thickness skin graft donor site.

- clefts and craniofacial malformations;
- skin, giant naevi, vascular malformations;
- urogenital;
- hand and limb malformations;
- miscellaneous:
 - Bell’s (facial) palsy;
 - pressure sores;
 - aesthetic surgery;
 - chest wall reconstruction.

A few key principles that can also be applied to other surgical specialties should be observed. In many reconstructions, success depends upon good rapid wound healing, which itself depends upon attention to detail from the surgeon. Adequate debridement, careful technique, gentle handling of tissues and consideration of blood supply are all key factors that influence outcome (Table 31.1).

The placement of incisions can be critical, especially in reducing the appearance of scars on the face and in areas of tension. When possible, incisions should lie in the lines of minimal tension (described by Langer, but frequently different from those originally noted) (Figure 31.5).

Table 31.1 Plastic surgery principles.

Optimise wound by adequate debridement or resection
Wound or flap must have a good blood supply to heal
Place scars carefully – ‘lines of election’ ^a
Replace defect with similar tissue – ‘like with like’ ^b
Observe meticulous surgical technique
Remember donor site ‘cost’

^aLines of election – analogous to Langer’s lines of minimal skin tension.

^bMillard DR. *Principles of plastic surgery*. Boston: Little & Brown, 1986.

Grafts

Grafts are tissues that are transferred without their blood supply, which therefore have to revascularise once they are in a new site. They include the following:

Figure 31.5 Lines of relaxed skin tension.

- **Split-thickness skin grafts (of varying thickness).** These are sometimes called Thiersch grafts. They are used to cover all sizes of wound, are of limited durability and will contract. They may be used to provide valuable temporary wound closure before better cosmetic secondary correction after rehabilitation.
- **Full-thickness skin grafts (Wolfe grafts).** Used for smaller areas of skin replacement where good elastic skin that will not contract is required (such as fingers, eyelids, facial parts).
- **Composite skin grafts (usually skin and fat, or skin and cartilage).** Often taken from the ear margin and useful for rebuilding missing elements of nose, eyelids and fingertips.

- **Nerve grafts.** Usually taken from the sural nerve, but smaller cutaneous nerves may be used.
- **Tendon grafts.** Usually taken from the palmaris longus or plantaris tendon (runs just anteromedial to the Achilles tendon) and used for injury loss or nerve damage correction.

Flaps

Flaps are tissues that are transferred with a blood supply. They therefore have the advantage of bringing vascularity to the new area. Flaps can be raised to consist of any specific tissue; for skin flaps the following will illustrate the types that exist (Figure 31.6):

- **Random flaps.** Three sides of a rectangle, bearing no specific relationship to where the blood supply enters; the length to breadth ratio is no more than 1.5:1. This pattern can be lengthened by 'delaying' the flap, a process in which the cuts are partially made and the flap is part lifted at a first operation; it is then replaced, thus 'training' the blood supply from a single border of the rectangle. At a second procedure, it is raised further and finally transferred.
- **Axial flaps.** Much longer flaps, based on known blood vessels supplying the skin. This technique was rediscovered in the 1960s and 1970s and enables many long thin flaps to be safely moved across large distances.
- **Pedicled/islanded flaps.** The axial blood supply of these flaps means that they can be swung round on a stalk or even fully 'islanded' so that the business end of the skin being transferred can have the pedicle buried (Figure 31.7).
- **Free flaps.** The blood supply has been isolated, disconnected and then reconnected using microsurgery at the new site (Figure 31.8).
- **Composite flaps.** Various tissues are transferred together, often skin with bone or muscle (osseocutaneous or myocutaneous flaps, respectively).

Figure 31.6 Skin flaps, from simple to complex.

Karl Thiersch, 1822–1895, Professor of Surgery, Leipzig, Germany. He was a pioneer of free skin grafts and described his method of skin grafting in 1874.

John Reissburg Wolfe, 1824–1904, ophthalmic surgeon, Glasgow, UK, described full thickness skin grafts in 1875 and in the same year used forearm skin to construct an eyelid.

Figure 31.7 (a–c) Islanded pedicled flap used from instep to resurface heel defect.

- **Perforator flaps.** This description refers to a whole new subgroup of axial flaps in which tissues are isolated on small perforating vessels that run from more major blood vessels to supply the surface.

Skin substitutes

One solution to the problem presented by major skin loss with inadequate skin donor sites has been to use artificially engineered skin substitutes. These vary from thin sheets of autologous keratinocytes, to artificial collagen matrices with embedded

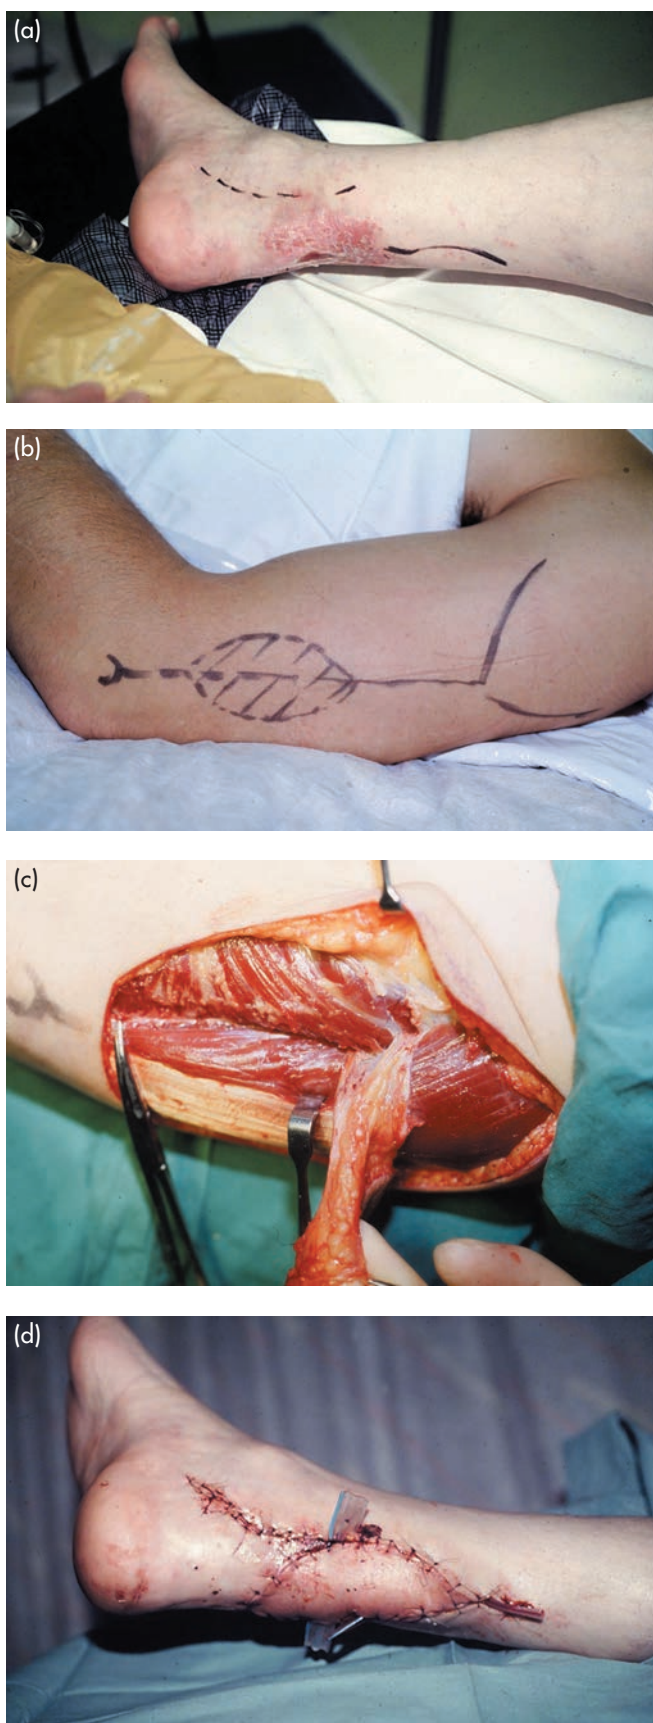

Figure 31.8 (a–d) Free lateral arm fasciocutaneous flap used to resurface a tendo Achilles defect.

fibroblasts and a keratinocyte sheet covering. They are costly, but are becoming widely used, and it is likely that tissue-engineered products will continue to be developed in an attempt to solve difficult reconstructive problems.

Tissue expansion

This technique is valuable in using 'local' tissue for reconstruction. The natural ability of tissue to expand has been harnessed clinically since the experiments of Austad and the clinical work of Radovan in the 1970s. It is a technique borrowed from nature, and it is observed during pregnancy when skin expands over the underlying mass. It involves placing a device – usually an expandable balloon constructed from silicone – beneath the tissue to be expanded and progressively enlarging the volume with fluid while the overlying tissue accommodates to the changed vascular pressure (Figure 31.9). The fluid (usually sterile saline coloured blue in Figure 31.9) is introduced via a self-sealing port attached to a filling tube that enters the balloon. It may be introduced as frequently as can be tolerated by the patient until the tissues are stretched enough to be used for reconstruction. The tissues expanded do not hypertrophy, but there are major changes in the collagen structure.

The process is time-consuming, although it can be very valuable in problematic cases. It is invaluable for sharing remaining areas of scalp hair after severe burns, removing major congenital skin naevi and restoring full-thickness skin over previously grafted limb wounds.

It must never be used under irradiated tissues (such as mastectomy sites), which will not expand but necrose (Summary box 31.2).

Summary box 31.2

Tissue expansion

Advantages

- Well-vascularised tissue
- Tissue next to defect, so likely to be of similar consistency
- Good colour match

Disadvantages

- Multiple expansion episodes (sometimes painful)
- Cost of device
- High incidence of infection and extrusion (especially limbs)

Vacuum-assisted closure

The use of negative pressure applied to a tissue defect has positive effects on wound closure, as well as making difficult and complex wounds more manageable during the early stages of granulation.

Figure 31.9 Tissue expander.

Exudate is removed and the suction pressure affects angiogenesis and tissue regeneration. The technique can be applied as part of early wound management before definitive surgical closure has been planned, or in some cases to avoid the need for surgery altogether. The foam sponge dressing is connected by a tube to a negative pressure pump that can be controlled to give intermittent suction (Figure 31.10).

Figure 31.10 VAC™ device used to temporarily close a sternal dehiscence prior to definitive debridement and flap cover.

Implants and prosthetics

Many tissue deficiencies cannot be adequately reconstructed with autologous tissue, however sophisticated the technique used. In such circumstances, implants are part of the reconstructive surgical 'toolbox'; they include solid and soft silicone materials, many forms of filler including collagen and polymers, and osseointegratable anchor points for prosthesis fixation.

The use of fat harvested using liposuction, centrifuged down and washed, then used to inject deficient areas around the body is now commonplace. It is a form of graft transfer since the cellular fluid regains vascularity in the host tissue. It is used for restoring contour deficits after injury and tumour treatment, as well as for cosmetic deformities.

ASSESSMENT AND DIAGNOSTIC PLANNING

Formation of a definitive treatment plan, carefully considering all available options for care with the whole of the patient's needs in mind, is a vital component of wise plastic surgical practice. This is never more so than when managing major trauma cases in the acute setting or when planning major cancer management, which might be staged over a period of treatments and procedures. If the reconstructive surgeon can be involved in early wound debridement and incisions, vital flap pedicles can be protected and the functional and cosmetic outcome made optimal. This pattern of shared team care has become the norm in many units demonstrating good outcomes from major trauma salvage.

The initial assessment of wounds involves adequate removal of devitalised tissue, assessment of which vital structures will

need reconstruction immediately and which might be better reconstructed later, and assessment of the degree of contamination involved, which will require further cleaning. Further planning will include the definitive soft-tissue cover of the wound and functional rehabilitation with full psychosocial rehabilitation.

TREATMENT AND COMPLICATIONS

Split-thickness skin grafts

Split-thickness skin grafts are taken with either hand-held (Figure 31.11) or powered skin knives (Figure 31.12). The most used donor site is the thigh, with the buttock preferable in children and cosmetically sensitive individuals. For larger grafts, almost any flat surface can be harvested, including the scalp if shaved (a very good and useful donor site). The thickness of the graft harvested, ease of graft 'take' and donor site healing must be weighed against the lack of durability of thin split-thickness skin grafts.

Split grafts can be perforated to allow exudates to escape and improve 'take'; they can be further meshed to allow expansion (Figure 31.13). This is carried out on a device that cuts a series of slits along the skin, allowing it to expand from a ratio of anything from 1:1.5 to about 1:6.

Grafts will only take on a bed on which they can become vascularised. Preparation of the wound bed is therefore an essential part of a successful graft (Figure 31.14). Graft failure is commonly caused by pus, exudate or residual dead tissue beneath the skin, haematoma or shearing forces. A clean healthy wound bed with a meshed graft tied in place to stop movement will encourage success. The group A β -haemolytic *Streptococcus* can destroy split grafts completely (and also convert a donor site to a full-thickness defect) and so the presence of this micro-organism is a contraindication to grafting.

Figure 31.11 Hand-held skin knife (a) and harvesting skin with hand-held knife (b).

Full-thickness skin grafts

Small dermal grafts (Wolfe grafts) can be taken from behind the ear, the groin creases and the neck, with easy direct closure of the donor site. Older people can sustain larger harvests because of skin laxity. Large full-thickness skin graft use is uncommon

Figure 31.12 Power dermatome harvest of a split-thickness skin graft, with the correct method of providing skin tension (a–d), and dressing of donor site with adhesive material (e).

Figure 31.13 Split-thickness skin graft mesher (a) and meshed skin applied to wound (b).

Figure 31.14 Cleaning a wound of excessive granulation tissue before grafting.

and requires great care to obtain a good take. Large donor sites require secondary split-thickness skin grafting. Major secondary burn contractures of the face and flexion creases can achieve remarkable functional and cosmetic improvement using such large grafts, particularly as the remaining facial muscle function can still produce a more natural appearance than when covered by a bulky full-thickness skin flap. Smaller full-thickness grafts are useful for contracture release around sensitive facial and extremity structures.

Technique

The shape of the graft needed is drawn and copied onto a small template (paper or cloth), which is used to transfer the same shape to the donor site. Full-thickness skin is cut; grafts take best if additional underlying fat is removed, after which the graft is applied with normal skin tension and tied down with a pressure dressing. The graft will remain vulnerable to shearing forces for several weeks after application.

Flaps

Local flaps

A local flap is raised next to a tissue defect in order to reconstruct it. Basic patterns include (Figure 31.15):

- **Transposition flap.** The most basic design, leaving a graftable donor site (Figure 31.16);
- **Z-plasty.** For lengthening scars or tissues;
- **Rhomboid flap.** For cheek, temple, back and flat surface defects;
- **Rotation flap.** For convex surfaces;
- **Advancement flap.** For flexor surfaces; may need triangles excised at the base to make it work (commonly called Burow's triangles);
- **V-to-Y advancement.** Commonly used for fingertips and extremities;
- **Bilobed flap.** For convex surfaces, especially the nose (Figure 31.17);
- **Bipedicle flap.** For eyelids, rarely elsewhere.

All flaps must be raised in the subcutaneous plane. Gentle undercutting of margins helps to close the donor site. The art of making local flaps work is to pull available local spare lax skin into the defect, so that the scar when closed sits in a good 'line of election'. Local flaps are usually not based on specific blood vessels, but are very useful in head and neck and smaller defect reconstructions. Good planning is essential to gain the best result from these flaps (Summary box 31.3).

Summary box 31.3

Local flaps

Benefits

- Best local cosmetic tissue match
- Often a simple procedure
- Local or regional anaesthesia option

Disadvantages

- Possible local tissue shortage
- Scarring may exacerbate the condition
- Surgeon may compromise local resection

TRANSPOSITION FLAP

Z-PLASTY

Two triangular transposition flaps interposed

(a)

Figure 31.15 Local flap diagrams. (a) Transposition and Z-plasty flaps; (b) bilobed and bipediced flaps; (c) rhomboid and rotation flaps. (continued opposite)

Combined local flaps

In some circumstances, such as burn contracture release, local flaps can usefully be combined to import surplus tissue from a wide area adjacent to a scar or defect that needs removal. Examples are the W-plasty and the multiple Y-to-V plasty, which is a very versatile means of releasing an isolated band scar contracture over a flexion crease (Figure 31.18).

Distant flaps

To repair defects in which local tissue is inadequate, distant flaps can be moved on long pedicles that contain the blood supply. The pedicle may be buried beneath the skin to create an island flap or left above the skin and formed into a tube.

The most common means of moving flaps long distances while still attached are with a long muscular pedicle that contains a dominant blood supply (a myocutaneous flap) (Figure 31.19) or with a long fascial layer that likewise contains a major septal blood supply (a fasciocutaneous flap) (Figure 31.20). These flaps can carry large composite skin parts for reconstruction very great distances, e.g. from the abdomen to the chest (for

breast reconstruction), from the chest to the face (for oral cancer reconstruction) and from the calf to the knee.

There are a vast number of carefully described myocutaneous and fasciocutaneous flaps throughout the body, all of which are based on known blood vessels. They are reliable when the anatomy of the blood supply is known by the surgeon and the skin is raised carefully in continuity with the underlying fascia or muscle, through which the small perforating vessels run to supply the piece of skin that is being transferred. They are the

'workhorse' of plastic surgery worldwide because they do not require complex equipment to raise them and they can solve the majority of reconstructive problems.

Microsurgery and perforator flaps

With fine instruments and materials, it has become commonplace to be able to disconnect the blood supply of the flap from its donor site and reconnect it in a distant place using the operating microscope.

Figure 31.17 (a–c) Example of a bilobed flap (in this case from nose to defect on tip following excision of a basal cell carcinoma). (d) Appearance at 6 weeks post-transfer.

Figure 31.18 (a and b) Y-to-V flap to release axillary contracture.

Figure 31.19 Trapezius pedicled myocutaneous flap to an area of recurrent squamous carcinoma in neck.

The free tissue transfer is now the best means of reconstructing major composite loss of tissue in the face, jaws, lower limb and many other body sites, as long as resources allow it (Figure 31.21). The operative procedure is similar whether the defect is newly produced from a recent injury or cancer resection or whether it is to be used for the secondary correction of a deformity, such as rebuilding a mastectomy deformity. At the site of the defect, the surgeon must be sure that all contaminated and dead tissue has been thoroughly cleared and cleaned, a process commonly described as debridement, although that term strictly refers to the release of constricting tissue. If this removal of poorly viable tissue is in doubt, then consideration should be given to delaying the reconstruction.

Figure 31.20 (a) Defect at ankle with the flap to be transferred outlined and the position of the perforating vessels (identified with hand-held Doppler device) marked with crosses; (b) flap raised with preserved septal perforators to skin paddle clearly visible; (c) flap rotated into position to cover the defect; proximal donor defect covered with a split-thickness skin graft (case courtesy of Mr David Johnson FRCS(Plast)).

The surgeon must then find a suitable blood supply for the tissue transfer at the site to be reconstructed. A good arterial flow in and venous return out, without external tissue pressure (such as from surrounding wound induration), is of paramount importance in achieving a successful transfer. The flap is then raised (Table 31.2) and transferred using magnification (Figure 31.22). Free muscle transfers should be reanastomosed within 1–2 hours if possible; fasciocutaneous flaps are more robust and can survive slightly greater ischaemic times (Summary box 31.4).

Summary box 31.4

Free tissue transfer (or free flap)

Advantages

- Being able to select exactly the best tissue to move
- Only takes what is necessary
- Minimises donor site morbidity

Disadvantages

- More complex surgical technique
- Failure involves total loss of all transferred tissue
- Usually takes more time unless the surgeon is experienced

Table 31.2 Common free tissue transfer donor sites.

Muscle only	Latissimus dorsi
	Rectus abdominis
	Gracilis
Myocutaneous	Latissimus dorsi
	Transverse rectus abdominis
Fasciocutaneous	Radial forearm flap
	Scapular
	Lateral arm
	Anterolateral thigh
	Groin
Osseous	Fibula (may be cutaneous as well)
	Forearm (taking sliver of radius bone)
	Iliac crest
Fascial	Temporoparietal
Miscellaneous	Jejunum – for oesophageal reconstruction
	Pectoralis minor – for facial reanimation
	Omentum – for chest wall and limb defects

Recent developments have led to surgeons dissecting distant flaps free from the carrier muscle or fascia, to reduce the donor morbidity further. These distant 'perforator' flaps increase the flexibility of the use of the flap tissue while reducing donor site problems. Future flap design is moving towards individualised flaps customised in freestyle fashion for the specific reconstructive requirement demanded.

Care of flaps and monitoring

After a flap has been moved, it should be observed for tissue colour, warmth and turgor, and be pressed to assess blanching and capillary refill time. Loss of arterial inflow results in pale, cold, flaccid tissue; loss of venous outflow results in blue conges-

Figure 31.21 (a–c) Large myocutaneous free flap (latissimus dorsi) to cover an exposed cranial defect following the excision of advanced basal cell carcinoma (case courtesy of Mr David Johnson FRCS(Plast)).

tion, increased turgor, rapid capillary refill and initially a warm flap. In a pedicled flap, such venous congestion may be relieved by releasing suture tension; applying leeches to suck out excess venous blood is a last resort when no other means of restoring venous drainage can be obtained.

The most common causes of flap failure are:

- poor anatomical knowledge when raising the flap (such that the blood supply is deficient from the start);
- flap inset with too much tension;
- local sepsis or a septicaemic patient;
- the dressing applied too tightly around the pedicle;
- microsurgical failure in free flap surgery (usually caused by problems with surgical technique)
- tobacco smoking by patient.

'Wet, warm and comfortable'

The best advice for postoperative flap care for major tissue transfers is to keep the patient 'wet, warm and comfortable'. This means that the patient should be well hydrated with a hyperdynamic circulation, a very warm body temperature and well-controlled analgesia to reduce catecholamine output.

Reconstructing complex areas

Certain areas, such as the eyelids, nose, lips, ears, genitalia, fingers, breast and intraoral structures, often require a combination of methods to produce the most functional and acceptable outcome for the patient. Planning such reconstruction involves considering each cosmetic subunit involved in the defect and bringing the best tissue to rebuild it. An example is the Indian forehead rhinoplasty of Sushruta, which involves transposition of a pedicled fasciocutaneous flap from forehead to nose, with the donor site usually thin skin grafted, but occasionally closed primarily in small flaps. It remains the finest means of transporting cosmetically correct tissue to the nose.

FUTURE TRENDS

Vascularised composite allografting

Plastic surgeons have long sought to use transplanted tissue to solve the problems posed by the most severe tissue defects. Esser, in the early twentieth century, pioneered much innovative surgery and urged research into this area. Later, Joe Murray, a plastic surgeon in the United States, undertook the first kidney transplant and was awarded the Nobel Prize for his work. Improved understanding of immunology and means of tolerance induction are now leading to the use of transplanted composite tissues for the most intractable cases of loss of tissue following injury and cancer. Limb transplantation in cases of multiple loss (especially following war injury) is becoming accepted practice in centres where all aspects of care including ethical considerations have been addressed. It is likely that sophisticated tolerance induction for donor-specific transplantation will be possible within the next decade, and lead to a rapid increase in the use of such procedures.

Tissue and bioengineering

Improved understanding of tissue behaviour is leading to numerous innovations in wound manipulation using biological

Johannes Fredericus Samuel Esser, 1877–1946 born in Leyden, Netherlands. A Dutch plastic surgeon who pioneered reconstructive surgery on soldiers wounded in the First World War. He is thought to have coined the term 'stent' in 1917 to describe his use of a dental impression compound invented in 1856 by the English dentist Charles Stent (1807–1885) to create a form for facial reconstruction.

Joseph E Murray, born 1919, Professor Emeritus of Plastic Surgery, Harvard University Medical School, Boston, MA, USA. He shared the 1990 Nobel Prize for Physiology or Medicine with E Donnall Thomas for his work on organ and cell transplantation. Murray's interest in transplantation began during his military service in the Second World War. The early experiences with skin transplantation for burns in pilots formed the basis for Murray's interest in solid organ transplantation. He performed the world's first kidney transplantation in identical twins in Peter Brent Brigham Hospital, Boston in 1954.

Figure 31.22 Large 'chimeric flap' of latissimus dorsi and serratus anterior muscles (a) to cover a complex open wound of the foot and ankle (b), illustrating the donor site (c and d) and fully covered defect (e and f) (case courtesy of Mr David Johnson FRCS(Plast)).

mechanisms. Tissue-engineered biological substitutes for tendon, nerve, larynx and other vital structures are becoming established, and will greatly influence the spectrum of reconstructive procedures in the coming years.

Novel polymers and biologically tolerated materials are also being developed to act as nerve conduits, facial muscle substitutes and self-inflating expansion devices. The interface of new material science with reconstructive surgery is still in its infancy.

CHAPTER 32

Disaster surgery

LEARNING OBJECTIVES

To recognise and understand:

- The common features of various disasters
- The principles behind the organisation of the relief effort and of triage in treatment and evacuation
- The role and limitations of field hospitals
- The features of conditions peculiar to disaster situations and their treatment

INTRODUCTION

Natural disasters such as floods and earthquakes provide a constant reminder of the awesome power and capricious nature of our planet. The depletion of the ozone layer and global warming mean that the future may hold in store natural events that will be even greater in magnitude than any of the ones that we have experienced before. Alongside the ravages of nature is our own propensity to damage our fellow man. National conflicts and ideological differences have not lessened over the millennia and the resultant 'unnatural disasters' have the potential to rival the natural ones in enormity and the impact on human life. The spectre of terrorist attacks constantly haunts security organisations and health-care providers.

COMMON FEATURES OF MAJOR DISASTERS

Any event that results in the loss of human life is disastrous, but most accidents, such as aeroplane and train crashes, are limited in the number of people involved. Conversely, earthquakes, tsunamis and nuclear explosions leave in their wake massive destruction over large areas, which may transcend national boundaries. All the apparatus of a society that responds to such disasters (the civil administration, emergency services, fire brigades and hospitals) may themselves also be

Figure 32.1 Damage to emergency medical services.

crippled (Figure 32.1). Large numbers of people may require immediate shelter, clean water and food before medical care can be considered.

A breakdown of communication is inevitable and is accompanied by widespread panic and a disruption of civil order. Access to the disaster area may be limited because of the destruction of bridges, road and rail links (Summary box 32.1).

FACTORS INFLUENCING RELIEF EFFORTS AND PROVISION OF MEDICAL AID

Communication is the critical factor that enables the authorities to respond quickly and appropriately. Wireless technology and satellite imagery have revolutionised the way in which real-time information can be obtained (Figure 32.2). Even so, there is an inevitable lag period between the occurrence of the disaster and the response from the establishment.

The location of the disaster area, whether rural or urban, has a significant bearing on relief efforts. Terrorist attacks and

Summary box 32.1

Common features of major disasters

- Massive casualties
- Damage to infrastructure
- A large number of people requiring shelter
- Panic and uncertainty among the population
- Limited access to the area
- Breakdown of communication

Figure 32.2 Satellite image showing destruction of a bridge as a result of flood.

nuclear events are more likely to be targeted towards large population centres where emergency and medical services are better developed. However, these areas are also densely populated and may have limited access by road and air. Natural disasters can strike anywhere, but can be particularly difficult to manage if they occur in remote areas because relief efforts are hampered by geographical isolation and the lack of a suitable infrastructure.

The time-frame in which a disaster occurs also has an impact on the relief efforts. Earthquakes and blasts unleash havoc in fractions of a second, but floods and hurricanes may continue

for several days and nuclear fallout can damage the ecosystem for years to come. Another important factor is the state of development of the country; disasters in the developing world can seldom be managed without significant outside assistance (Summary box 32.2).

Summary box 32.2

Factors influencing rescue and relief efforts

- Status of communications
- Location, whether rural or urban
- Accessibility of the location
- Time-frame in which disaster occurs
- Economic state of development of the area

SEQUENCE OF RELIEF EFFORTS AFTER A DISASTER

Establishing a chain of command

Many countries have organisations that deal with disasters, such as the Federal Emergency Management Authority (FEMA) in the United States. In others, an ad-hoc administrative hierarchy is established to coordinate the efforts of the teams participating in relief efforts. The actual organisation that deals with a particular disaster will depend upon the circumstances, but the principles are similar (Figure 32.3).

Damage assessment

The first objective in disaster management is an accurate assessment of the damage and the number of casualties. All sources

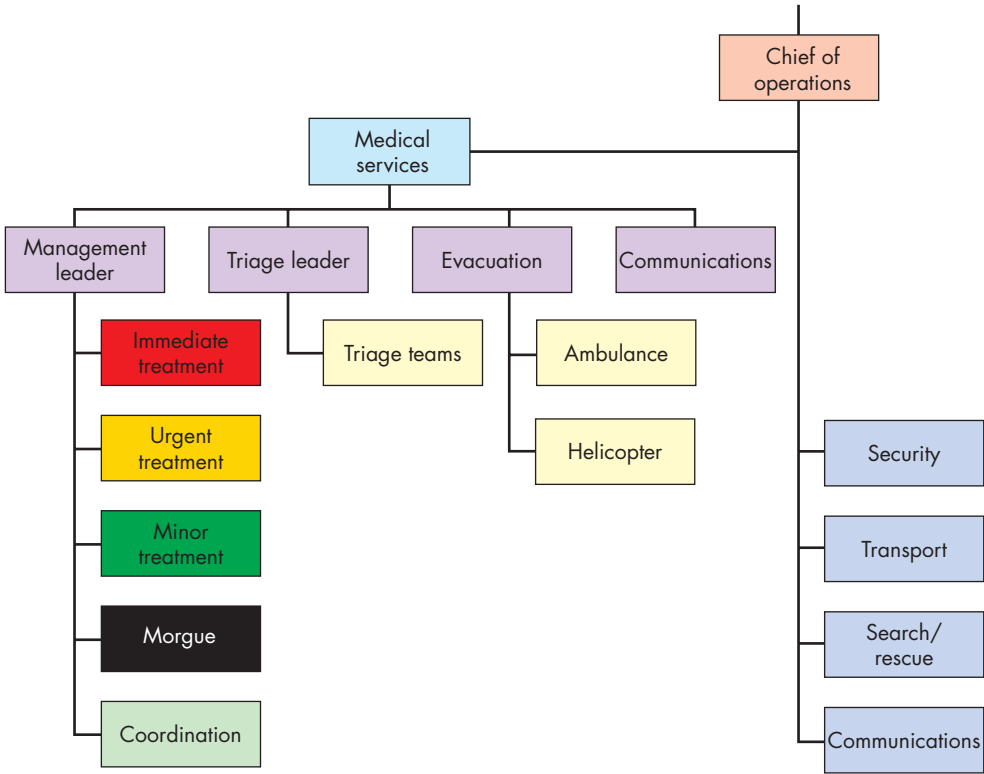

Figure 32.3 Organisation chart for disaster management.

of information must be employed, not just the official channels. The 24-hour news services are frequently the first on the scene and can be an important source of information.

Mobilising resources

The next step is mobilisation of human and material resources appropriate to the size and nature of the disaster. Although all modes of transport available need to be considered, helicopters provide the quickest access for the first responders (Figure 32.4). The teams who make up the initial response must include experienced staff who can assess the situation and have the authority to take immediate decisions and organise further assistance.

Rescue operation

Early coordination of the rescue effort allows optimal use of limited resources. Rescue teams from the outside can complement local volunteers who are familiar with the area. The first priority is to prevent further damage from occurring, both to people and to the infrastructure. Fires should be put out, people moved away from falling debris and well-meaning non-professionals stopped from embarking on hazardous rescue efforts.

The types of injuries encountered by rescue workers depends

upon the delay between the onset of the disaster and their arrival. Patients with head injuries and abdominal and thoracic trauma will either have been treated or have succumbed to their injuries within 48–72 hours of a disaster. After the first 2 weeks, the only casualties requiring treatment are those with complex limb trauma, and infected wounds (Figure 32.5).

Coordination with relief agencies

A laudable aspect of globalisation is the outpouring of help from governments and non-governmental organisations (NGO) in response to a disaster on the other side of the world. Some, like Rescue and Preparedness in Disasters (RAPID), deal with search and rescue whereas others, like the International Committee of the Red Cross (ICRC) and Oxfam, provide general disaster-related relief (Figure 32.6). United Nations (UN) agencies, such as the World Health Organization (WHO), the World Food Programme (WFP) and the UN High Commissioner for Refugees (UNHCR) deal with medical care, food provision and refugees, respectively. Coordinating the efforts of these organisations is essential for optimal results, as medical aid in isolation is inadequate without the simultaneous provision of safe drinking water, food, clothing and shelter. Rescue teams should be prepared to be self-sufficient and not rely on the local infrastructure, which will be stretched to the limit if not completely destroyed (Summary box 32.3).

Figure 32.4 Heli-evacuation.

Summary box 32.3

Sequence of the relief effort in major disasters

- Establish chain of command
- Set up lines of communication
- Carry out damage assessment
- Mobilise resources
- Initiate rescue operation
- Triage casualties
- Start emergency treatment
- Arrange evacuation
- Start definitive management

Figure 32.5 Time-line showing the type of injuries encountered at different times in a disaster.

Figure 32.6 Oxfam and the International Committee of the Red Cross provide generalised relief.

Safety of the helpers

Rescue and relief workers are a diverse group of volunteers and may have little experience of dealing with the breakdown in civil order that occurs in the wake of disasters. It is not uncommon to encounter mobs looting stores of food and other essentials, especially if help has arrived late. This results in injuries, occasionally serious, to personnel trying to provide an equitable distribution of goods. It is therefore imperative that the local authorities make it a point to safeguard the lives and property of aid workers to allow them to work without duress and fear.

Dealing with the media

Disasters act like a magnet for the news media and, in today's world of 24-hour news coverage, it exerts a powerful influence in shaping public opinion. It is frequently accused of dramatising situations and emphasising the inadequacies of the relief effort. Aid workers may find dealing with the media difficult as their priorities are rightly different. Nevertheless, it is essential to establish a working relationship between the two groups. With careful handling, the media can become a powerful ally and play a constructive role in identifying problems, galvanising aid and keeping the public informed.

Triage

Derived from the French verb '*trier*', triage means 'to sort' and has been the cornerstone of the management of mass casualties since the Napoleonic Wars. It aims to identify the patients who will benefit the most by being treated the earliest, ensuring the greatest good for the greatest number. In a broader sense, it determines who will be treated first, what mode of evacuation is best and which medical facility is optimal for the management of the patient. Numerous studies show that only 10–15 per cent of disaster casualties are serious enough to require hospitalisation. By sorting out the minor injuries, triage lessens the immediate burden on medical facilities. Deciding who should receive priority when faced with hundreds of seriously injured victims is a daunting prospect. Senior doctors tend to believe that their services are better utilised in the actual management of patients, rather than in triage. This is a mistake and it is crucial that this task be undertaken by someone senior, who has the training and experience, and authority to make these critical decisions.

To keep pace with the changing clinical picture of an injured person, triage needs to be undertaken at several levels, i.e. in the field, before evacuation and at the hospital.

Triage areas

For efficient triage, the injured need to be brought together into any undamaged structures that can shelter a large number of wounded. Examples are school buildings and stadia. A good water supply, lighting and ease of access are useful. Separate areas should be reserved for patient holding, emergency treatment and decontamination (in the event of discharge of hazardous materials). An area should also be designated to serve as a morgue, preferably a little removed from the holding and treatment areas.

Practical triage

Emergency life-saving measures should proceed alongside triage and actually help the decision-making process. The assessment and restoration of airway, breathing and circulation are critical and are discussed in Chapter 24. A simple visual check of the injuries of each casualty is notoriously unreliable. Vital signs and a general physical examination should be combined with a brief history taken by a paramedic, or volunteer worker if one is available.

Documentation for triage

Accurate documentation is an inseparable part of triage and should include basic patient data, vital signs with timing, brief details of injuries (preferably on a diagram) and treatment given. In addition, a system of colour-coded tags attached to the patient's wrist or around the neck should be employed by the emergency medical services. The colour denotes the degree of urgency with which a patient requires treatment (Figure 32.7).

Triage categories

All methods of triage use simple criteria based on vital signs. A rapid clinical assessment should be made taking into account the patient's ability to walk, their mental status and the presence or absence of ventilation or capillary perfusion. A commonly used four-tier system is presented in Table 32.1. Triage carries serious consequences, especially for patients who are consigned to the unsalvageable category. It should be carried out with compassion, but should also be quick, clear and decisive.

Evacuation of casualties

Decisions regarding the best destination for each patient need to be based on how far it is safe for them to travel and whether the facilities that they need for definitive treatment will be available. A quick retriage is very useful in this situation. The paramedics accompanying the casualties should be familiar with safe transport techniques to prevent the 'second accident' (damage caused inadvertently by transport and treatment). A patient with a spinal injury should be strapped to a spine board, the hard collar adjusted and the head fixed to the board with tape. Chest tubes, urinary catheters, endotracheal tubes, tracheotomy tubes and intravenous lines must be properly secured. For patients obliged to travel for a long time, an adequate supply of essentials, such as intravenous fluids, dressings, pain medication and oxygen, must be arranged. For unaccompanied minor children, their details must be clearly documented and social services informed (Summary box 32.4).

Triage is the earliest example of clinical risk management. This is done on the basis of need so that resources can be allocated by good prioritisation. The process was first used in 1792 by Baron Dominique Jean Larrey, Surgeon in Chief to Napoleon's Imperial Guard. The concept of triage emerged from the French Service de Sante so that resources could be used to the optimum – 'most for the most'.

Table 32.1 Triage categories.

Priority	Colour	Medical need	Clinical status	Examples
First (I)	Red	Immediate	Critical, but likely to survive if treatment given early	Severe facial trauma, tension pneumothorax, profuse external bleeding, haemothorax, flail chest, major intra-abdominal bleed, extradural haematomas
Second (II)	Yellow	Urgent	Critical, likely to survive if treatment given within hours	Compound fractures, degloving injuries, ruptured abdominal viscus, pelvic fractures, spinal injuries
Third (III)	Green	Non-urgent	Stable, likely to survive even if treatment is delayed for hours to days	Simple fractures, sprains, minor lacerations
Last (O)	Black	Unsalvageable	Not breathing, pulseless, so severely injured that no medical care is likely to help	Severe brain damage, very extensive burns, major disruption/loss of chest or abdominal wall structures

Summary box 32.4**Essentials of casualty evacuation**

- Retriage to upgrade priorities among the injured
- Select appropriate medical facilities for transfer
- Choose appropriate means of transport
- Prevent the 'second accident' during transfer
- Ensure an adequate supply of materials to accompany the patient

Field hospitals

The need for field hospitals depends upon the location, the number of casualties and the speed with which evacuation can be organised. The two basic types of field hospitals are (1) the traditional tented structure and (2) the modular type housed in containers (Figure 32.8).

The modular type is self-contained and can be operational as soon as it reaches the disaster area, but the containers are heavy and require an intact road or rail link. The tented structures require an initial period of setting up, but they are very portable and the components can be carried in small vehicles or air dropped. Whichever type is chosen, the facility must be equipped with an x-ray plant, operating rooms, vital signs moni-

tors, sterilising equipment, a blood bank, ventilators and basic laboratory facilities.

Management in the field

Field hospitals principally function in three main areas (Table 32.2).

First aid

Care for patients with minor injuries involves cleaning wounds, suturing lacerations, splinting simple fractures and sprains, and applying bandages to cuts and bruises. Most of these 'walking wounded' can be sent away with antibiotics and simple pain relief. They can be asked to arrange follow up at their usual hospital or the field hospital.

Damage control surgery

Damage control surgery is the concept that in the temporary surgical facility closest to the injured, only the minimum amount of surgery should be performed to allow safe transfer of a patient to a definitive treating facility (see also Chapter 28).

This will include ensuring that the airway is secure, haemorrhage is under control, compartments are decompressed in the chest, skull, abdomen and limb compartments, and any contamination is prevented from developing into infection (Summary box 32.5).

Table 32.2 Type of treatment given in field hospitals.

	Examples	Further
First aid	Suturing cuts and lacerations, splinting simple fractures	Review at local hospital
Emergency care for life-threatening injuries	Endotracheal intubation, tracheotomy, relieving tension pneumothorax, stopping external haemorrhage, relieving an extradural haematoma, emergency thoracotomy/laparotomy for internal haemorrhage	After damage control surgery, transfer patients to base hospitals once stable
Initial care for non-life-threatening injuries	Debridement of contaminated wounds, reduction of fractures and dislocations, application of external fixators, vascular repairs	Transfer patients to base hospitals for definitive management

Figure 32.8 Field hospitals: (a) and (b) modular type; (c) tented structure; (d) interior of a tented field hospital.

Summary box 32.5

Principles of damage control surgery

- Do the minimum needed to allow safe transfer to definitive facility
- Take actions which prevent deterioration of that patient during transfer
- Secure the airway (tracheostomy?)
- Control bleeding (craniotomy, laparotomy, thoracotomy, repair major limb vessels?)
- Prevent pressure build up (burr holes, chest drain, laparotomy, fasciotomy?)
- Prevent infection by extensile exposure and removing dead and contaminated tissue

Emergency care for immediate life-threatening injuries

There are many patients who may be saved by relatively simple measures provided that these are taken urgently. Endotracheal intubation and tracheotomy may be needed to provide a secure airway. A needle thoracocentesis will relieve a tension pneumothorax, and a chest drain will be needed before a patient with a significant chest injury is transferred by air. An open pneumothorax should be closed. A clam-shell thoracotomy can be used by all surgeons to open a chest rapidly when dealing with cardiac

tamponade or major vessel damage in the thorax (Chapter 28). A laparotomy may be needed to isolate loops of bowel with penetrating injuries (simply staple across the bowel each side of the perforation). Excision and reanastomosis of damaged bowel can be left for definitive surgery later. If the abdomen is opened, it is probably best left open and covered with a sterile plastic sheet, during transfer to definitive care (Opsite closure). This will prevent the development of abdominal compartment syndrome, as well as saving time. Burr-holes will be needed if intracranial pressure is rising and is thought to be the result of an extradural haemorrhage, but a flap should not be raised (see Chapter 25). Damaged major vessels to limbs should be repaired if possible. Faciotomies will be needed for muscle compartments which are swelling from injury or from reperfusion. Amputation for clearly devitalised limbs and gas gangrene should be undertaken at field hospitals as delay will be fatal.

Initial care for non-life-threatening injuries

Many patients present with serious injuries that require complex, prolonged care. Compound limb fractures, degloving injuries, dislocations of major joints, major facial injuries and complex hand injuries all fall into this category. These patients will need specialised care requiring transfer to the appropriate facility. Replantations of amputated limbs and other extensive reconstructive procedures should not be attempted in field hospitals as they are time consuming and divert resources and personnel to

the treatment of a few patients. The decision as to what constitutes damage control surgery and what should be left for definitive care will have to be made at the time and will depend on the number of casualties, the resources available and the logistics of transport to a definitive care facility.

Debridement

Debridement has come to mean more than simply the laying open of tissues. It plays a crucial part in the management of trauma. Wounds sustained in disasters are often heavily contaminated, containing foreign bodies and non-viable tissues (Figure 32.9). Debridement reduces the chances of anaerobic and necrotising infections and can prevent systemic sepsis. The following principles of debridement apply to all contaminated wounds, including gunshot and shrapnel injuries:

- It should be undertaken in a sterile environment with good lighting by surgeons who are well versed in trauma surgery.
- After the administration of anaesthesia, the first step is opening and cleaning of the injured area by copious irrigation with normal saline. Pulse lavage, if available, is ideal for this but a large syringe can also be used (Figure 32.10). Next, the wound is palpated and all foreign matter is lifted out using forceps. In-driven dirt is best removed using a nail brush as even small particles of retained dirt result in permanent tattooing. Dirt intimately enmeshed in the soft tissues can only be removed by excision of those contaminated tissues. Open joints should be thoroughly irrigated and all foreign material removed.

Figure 32.9 Gross contamination typically seen in wounds sustained in disasters. The radiograph shows numerous radio-opaque foreign bodies in the soft tissues.

Figure 32.10 Lavage with normal saline to decontaminate a wound.

- Wounds with a small external opening but more extensive cavitation (firearm and other high-impact injuries) should be generously enlarged in a longitudinal direction (along with the deep fascia) in order to gain better access, and to allow full decompression of the underlying muscles. This should preferably be carried out under tourniquet to reduce blood loss. This extensile exposure helps to visualise the damaged structures and allows the surgeon to gain proximal and distal control of vascular injuries, and to identify severed ends of major nerves and tendons.
- The next step is excision of all dead and devitalised tissue. It is advisable at this stage to let down the tourniquet to check the vascularity of the tissues. Skin excision should be kept to a minimum as it is quite resistant to trauma and only the margins of the wound need to be trimmed back to healthy bleeding edges. Removal of devitalised muscle is important and should be undertaken generously. Muscle that is pale or dark in colour, has a soft consistency, does not contract on pinching, and does not bleed on cutting is definitely non-viable and must be removed if the risk of gangrene is to be minimised. Small pieces of crushed bone lying free should be removed. Large segments of bone that retain some soft-tissue attachment should be left undisturbed. In patients with traumatic amputations, the bone ends are tidied, the skin and muscle edges trimmed to the lowest level possible and the wound left open.
- In patients with associated fractures, skeletal stabilisation should be obtained before embarking on any repairs. External fixators are invaluable for this and make wound management much easier (Figure 32.11).
- In major trauma in the acute setting, only vascular repairs are justified. For lacerated vessels, the ends are trimmed and an anastomosis performed. In the case of loss of substance of the vessel wall a vein patch or reversed vein graft may be employed. Silicone tubing may be used as a temporary bypass (stent) while vascular repair is being carried out in patients with critically compromised distal circulation.
- Nerves and tendons should not be dissected out, nor any attempt made at definitive repair in wounds with tissue devitalisation and gross oedema, as it leads to poor results. The key structures should simply be identified and the edges trimmed and tagged with non-absorbable sutures to facilitate repair during subsequent exploration.

Figure 32.11 External fixators provide skeletal stabilisation and allow easy management of the soft tissues.

Summary box 32.6

Principles of debridement and initial wound care

- Obtain generous exposure through skin and fascia
- Identify neurovascular bundles
- Excise devitalised tissue
- Remove foreign bodies
- Repair major vessels
- Obtain skeletal stabilisation with external fixators
- Only tag tendons and nerves which have been cut
- Leave the wound open and delay primary closure
- Avoid tight dressings
- Elevate the injured limb

- Wounds sustained in disasters are heavily contaminated and therefore are not suitable for primary closure. However, blood vessels (whether repaired or simply exposed) and exposed joint surfaces need to be covered. This can be achieved by loosely tacking adjoining muscle over the exposed area. The wound is then covered with fluffed gauze and sterile cotton and the extremity splinted with a plaster of Paris slab, even if there is no fracture. For the upper extremity, elevation with a drip stand and, for the lower limb, elevation on a couple of pillows are important to reduce oedema.
- Broad-spectrum antibiotics, such as third-generation cephalosporins, are started prophylactically and continued for 5–7 days.
- The wound should be reinspected at 24–48 hours to assess the viability of the tissues and the distal circulation. The wounds are closed between the fourth and sixth day if there is no infection. Tension should be avoided and you should not hesitate to use partial thickness skin grafts to obtain cover. Skin staplers are particularly useful and save time when dealing with large numbers of casualties.
- In wounds with gross infection, no attempt at closure is made until infection is eradicated. These wounds are re-explored to make sure that there are no residual foreign bodies or devitalised tissue. Surface swabs are not useful, but tissue should be taken for microbiological culture. Vacuum-assisted closure (Vac-Pac) has emerged as a very useful tool for irregular and deeply cavitating wounds. It utilises low-pressure suction to evacuate exudate, promote granulation tissue and reduce the size of the wound (Figure 32.12). Once the wounds are free from infection secondary closure can be undertaken (Summary box 32.6).

Figure 32.12 Use of low-pressure vacuum therapy in preparing a wound for secondary closure.

DEFINITIVE MANAGEMENT

Definitive management is undertaken at major hospitals. They should be given as much notice as possible as to the expected number of casualties so that the staff are prepared. The hospitals to which casualties are sent should be selected on the basis of the facilities available and the number of injured that they can handle. The actual number of beds available is seldom a good guide to capacity, as the ancillary resources required for trauma patients are more than for the typical case mix of a hospital. A rule of thumb is that only half the bed strength of a hospital can be utilised to provide optimum trauma care in an emergency situation.

Hospital reorganisation

In hospitals receiving mass casualties during disasters, some reorganisation of services is unavoidable. This includes transferring patients with non-urgent conditions to other facilities, augmenting surgical services, reorganising the specialist rota and redesignating medical wards as surgical care areas to accommodate the patient load. A quick check of hospital inventories should be undertaken to ensure availability of essential equipment and medicines. An appeal for blood donations should be broadcast.

SPECIFIC ISSUES

There is no injury that is peculiar to disasters. Destruction of buildings and explosions can produce the whole spectrum of external injuries from minor cuts to extensive degloving,

compound fractures and amputations. Internal organ damage is frequent and, unless immediate help is available, this accounts for the major share of early mortality figures. People trapped under fallen buildings may suffer crush injuries and crush syndrome if the duration is prolonged. Those near an explosion can suffer injury to the lungs and abdominal viscera, as well as burns, because of the heat of the blast.

Crush injuries and missile injuries cause extensive tissue damage and gross contamination, both favourable conditions for anaerobic and microaerophilic infections.

Limb salvage

The Mangled Extremity Severity Score (MESS) and its modifications are useful in making a judgement about limb salvage. In the past, extensive tissue loss, neurovascular damage and loss of long fragments of bone were all considered indications for amputation. Currently, with the use of microvascular flaps, wounds of any dimension can be covered with healthy tissue in a single stage. If performed in time, vascular repairs can salvage most acutely ischaemic limbs. Distraction osteogenesis and vascularised bone transfers can restore bony continuity in all but the most massive bone losses. In view of these developments the indications for amputation in trauma have undergone a paradigm shift and the majority of patients who reach a tertiary-care facility within 24 hours are candidates for limb salvage (Figure 32.13). This assumes that debridement and, if required, vascular repairs have been performed in a field medical facility. Restoration of vascular continuity is the critical issue. A limb is unlikely to survive if vascular repairs of major limb vessels has been delayed for more than 4–6 hours.

Facial injuries

The management of facial injuries follows the same general principles of debridement and delayed closure as already outlined. Because of the functional and cosmetic importance of facial structures, skin and soft-tissue excisions are kept to a minimum. There is a robust blood supply to the face and the ability to counter infection is therefore very high. Even in patients who present late with gross contamination, a careful debridement followed by delayed primary closure can lead to good results (Figure 32.14).

Tetanus

This potentially fatal condition, also called 'lockjaw', is caused by *Clostridium tetani*, a Gram-positive spore-forming bacillus occurring naturally in the intestines of humans and animals and in the soil. It enters the body through a wound and replicates, thriving on the anaerobic conditions present in devitalised tissues. It produces tetanospasmin, a potent exotoxin that binds to the neuromuscular junctions of the central nervous system neurones, rendering them incapable of neurotransmitter release. This leads to failure of inhibition of motor reflex responses to sensory stimulation. The result is generalised contractions of agonist and antagonist muscles causing tetanic spasms. The median incubation period is 7 days, ranging from 4 to 14 days (Summary 32.7).

Figure 32.13 Badly traumatised lower limb. Reconstruction has been performed using a microvascular rectus abdominis flap covered with a skin graft.

Figure 32.14 Late-presenting facial injury with gross contamination. A thorough debridement followed by delayed primary closure has yielded good results.

Summary box 32.7

Tetanus

- Caused by *Clostridium tetani*
- Spores are present in the soil
- Thrives in dead or contaminated tissue
- Produce tetanospasmin, an exotoxin
- Produces spasm of muscles
- Make sure patients are immunised
- For heavily contaminated wound, give anti-tetanus globulin

Early symptoms are painful spasms of the masseter and facial muscles resulting in the classical risus sardonicus (Figure 32.15). The spasms spread to involve the muscles of respiration and the

laryngeal musculature. Spasms of the paravertebral and extensor limb musculature produce opisthotonus, an arching of the whole body. Laryngeal muscle spasm leads to apnoea and, if prolonged, to asphyxia and respiratory arrest. The spasms can be brought on by the slightest of sensory stimulus. They may be sustained and severe enough to produce long-bone fractures and joint dislocations.

The diagnosis is obvious once it is fully manifest. There are three aspects of management:

- **Prevention.** Wounds contaminated with soil are likely to harbour the tetanus spores, and active immunisation is indicated by administering 0.5 mL of tetanus toxoid intramuscularly. Patients with gross contamination of deeply cavitating wounds should also receive 250–500 units of human

Figure 32.15 Risus sardonicus of 'lockjaw' (courtesy of Dr Samira Ajmal FRCS).

anti-tetanus globulin (ATG) intramuscularly to provide passive immunisation and to neutralise the circulating toxin. In full-blown clinical tetanus, 3000–10 000 units of ATG should be administered. Wound manipulation should be avoided for 2–3 hours after ATG administration to minimise tetanospasmin release.

- **Local wound care.** This includes a thorough wound debridement to eliminate the anaerobic environment. Intravenous administration of 10–24 × 106 units per day of penicillin G should be continued for 10–14 days. The wound should be closed using the delayed primary or secondary closure techniques (see above under Debridement).
- **Supportive care for established disease.** These patients are nursed in an intensive care unit (ICU) environment, free from strong sensory stimuli. Unnecessary manipulations are avoided. Diazepam is useful in preventing the onset of spasms but if these become frequent and sustained the patient should be paralysed, intubated and placed on a ventilator. The patient is then gradually weaned off the ventilator under cover of anticonvulsants. The overall mortality rate is around 45 per cent, prognosis being determined by the incubation period and the time from the first symptom to the first tetanic spasm. In general, shorter intervals indicate a poorer prognosis.

Necrotising fasciitis

Necrotising fasciitis is a dangerous and rapidly spreading infection of the fascial planes leading to necrosis of the subcutaneous tissues and overlying skin. It is caused by β -haemolytic streptococci and, occasionally, *Staphylococcus aureus*, but may take the form of a polymicrobial infection associated with other aerobic and anaerobic pathogens, including *Bacteroides*, *Clostridium*, *Proteus*, *Pseudomonas* and *Klebsiella*. It is termed Fournier's gangrene when it affects the perineal area, and Meleney's synergistic gangrene when it involves the abdominal wall. The underlying pathology is identical wherever it occurs and includes acute inflammatory infiltrate, extensive necrosis, oedema and thrombosis of the microvasculature. The area becomes oedematous, painful and very tender. The skin turns dusky blue and black secondary to the progressive underlying thrombosis and necrosis (Figure 32.16). The area may develop bullae and progress to overt cutaneous gangrene with subcutaneous emphysema. It

spreads to contiguous areas but occasionally also produces skip lesions that later coalesce. It is accompanied by fever and severe generalised toxicity. Renal failure may occur as a result of hypovolaemia and cardiovascular collapse caused by septic shock. The rate of progression can catch the unwary by surprise and unless aggressively treated it leads to serious consequences with a mortality rate approaching 70 per cent (Summary box 32.8).

The diagnosis is usually made on clinical grounds. Creatinine kinase levels may show enormous elevation and biopsy of the fascial layers will confirm the diagnosis. Patients should

Figure 32.16 (a) Necrotising fasciitis at presentation and (b) rapid progression seen after 24 hours. (c) Typical bullae and induration.

Summary box 32.8**Necrotising fasciitis**

- Caused by beta-haemolytic strep or is polymicrobial
- Also called Fournier's or Meleney's gangrene
- Progress is rapid and renal failure is an early complication
- Treat with radical surgical excision repeated every 24 hours
- Give oxygen and penicillin

be admitted to the ICU and treated aggressively with careful monitoring of volume derangements and cardiac status. Oxygen supplementation is beneficial and endotracheal intubation is required in patients unable to maintain their airway.

High-dose penicillin G along with broad-spectrum antibiotics, such as third-generation cephalosporins and metronidazole, should be given intravenously until the patient's toxicity abates. The cornerstone of management is surgical excision of the necrotic tissue. The fascial planes are opened with ease as the infection produces inflammatory degloving and the yellowish-green necrotic fascia is visible. Devitalised tissue should be removed generously, preferably going beyond the area of induration. This can lead to profuse bleeding and it is wise to have blood already cross-matched. The wound is lightly packed with fluffed gauze and then dressed. This process should be continued on a daily basis as the necrosis is prone to spread beyond the edges of the excised wound. In patients who survive, this results in a large wound, which will require skin grafting or flap coverage.

Recently, the role of hyperbaric oxygen (HBO) has become more established. It is claimed that it is bactericidal, improves neutrophil function and promotes wound healing. The patient is placed in a high-pressure chamber and 100 per cent oxygen administered at a pressure of 2–3 atmospheres. Studies have shown a reduction in mortality rate in patients treated with HBO (9–20 per cent) compared with patients who did not receive HBO (30–50 per cent). The main limitation to its use is availability of the pressure chamber.

Gas gangrene

Gas gangrene is a dreaded consequence of inadequately treated missile wounds, crushing injuries and high-voltage electrical injuries. It is a rapidly progressive, potentially fatal condition characterised by widespread necrosis of the muscles and subsequent soft-tissue destruction. The common causative organism is *Clostridium perfringens*, a spore-forming, Gram-positive saprophyte that flourishes in anaerobic conditions. Other organisms implicated in gas gangrene include *C. bifermentans*, *C. septicum* and *C. sporogenes*. They are present in the soil and have also been isolated from the human gastrointestinal tract and female genital tract. Non-clostridial gas-producing organisms, such as coliforms, have also been isolated in 60–85 per cent of cases of gas gangrene (Summary box 32.9).

Clostridium perfringens produces many exotoxins, but their exact role is unclear. Alpha-toxin, the most important, is a lecithinase, which destroys red and white blood cells, platelets, fibroblasts and muscle cells. The phi-toxin produces myocardial suppression while the kappa-toxin is responsible for the destruction of connective tissue and blood vessels.

Wounds which have become contaminated with clostridial spores then become infected if devitalised tissue, foreign bodies or premature wound closure provide the anaerobic conditions

Summary box 32.9**Gas gangrene**

- Caused by *Clostridium perfringens*
- Spores are present in the soil
- Thrives in anaerobic conditions and produces many exotoxins
- Treat with radical and regular surgical excision
- Give oxygen and penicillin
- Early amputation may be life-saving

necessary for spore germination. The usual incubation period is <24 hours, but it can range from 1 hour to 6 weeks. A vicious cycle of tissue destruction is initiated by rapidly multiplying bacteria and locally and systemically acting exotoxins. Locally, this results in spreading necrosis of muscle and thrombosis of blood vessels while progressive oedema further compromises the blood supply. The typical feature of this condition is the production of gas (composed of nitrogen, hydrogen sulphide and carbon dioxide) that spreads along the muscle planes. Systemically, the exotoxins cause severe haemolysis and, combined with the local effects, this leads to the rapid progression of the disease, hypotension, shock, renal failure and acute respiratory distress syndrome (ARDS).

The earliest symptom is acute onset of pain that increases in severity as the myonecrosis progresses. The limb swells up and the wound exudes a serosanguinous discharge. The skin is involved secondary to underlying muscle necrosis, turning brown and progressing to a blue-black colour with the appearance of haemorrhagic bullae (Figure 32.17). The characteristic sickly sweet odour and soft tissue crepitus caused by gas production appear with established infection, but the absence of either does not exclude the diagnosis. These local signs are accompanied by pyrexia, a tachycardia disproportionate to body temperature, tachypnoea and alteration in mental status.

The diagnosis is made on the basis of history and clinical features: a peripheral blood smear may suggest haemolysis; a Gram stain of the exudate reveals large Gram-positive bacilli without neutrophils; and the biochemical profile may show metabolic acidosis and renal failure. Radiography can visualise gas in the soft tissues and computed tomography (CT) scans are useful in patients with chest and abdominal involvement.

Patients should be admitted to the ICU and treated

Figure 32.17 Typical picture of spreading gas gangrene caused by crush injury.

aggressively with careful monitoring. High-dose penicillin G and clindamycin, along with third-generation cephalosporins, should be given intravenously until the patient's toxicity abates. The mainstay of management is early surgical excision of the necrotic tissue. The muscle planes are opened through generous longitudinal incisions and all devitalised tissue is removed, going beyond the area of induration. Excision should be continued daily until the process of necrosis has stopped spreading. In established gas gangrene with systemic toxicity, amputation of the involved extremity is life saving and should not be delayed. No attempt is made at closure, amputation stumps are left open and the wound is lightly packed with saline-soaked gauze and then dressed.

The role of HBO is not as clear as in necrotising fasciitis, but it is recommended in severe cases if the facilities are available.

Blast injuries

Mechanism of explosive blast injury

The explosive pressure accompanying the bursting of bombs or shells ruptures their casing and imparts a high velocity to the fragments. These can cause even more devastating injury to the tissues than bullets. In addition, all explosions are accompanied by a complex blast wave composed of a blast pressure wave (dynamic overpressure) and the mass movement of air (blast wind). A mass movement of air from the rapid expansion of gases at the centre of the explosion displaces air at supersonic speed. This results in injury patterns ranging from traumatic amputation to total body disruption. When a blast pressure wave hits the body, the force of the impact sets up a series of stress waves that are capable of internal injury, particularly at air–fluid interfaces. Thus, injury to the ear, lungs, heart and, to a lesser extent, the gastrointestinal tract is notable (Summary box 32.10).

Summary box 32.10

Blast injuries

- Each fragment is a high velocity missile
- The blast wave hits air–fluid interfaces and bursts them
- Explore and fully excise each wound as all are likely to be heavily contaminated

General management of blast injuries

The structures injured by the primary blast wave, in order of prevalence, are the middle ear, the lungs and the bowel. However, the most common urgent clinical problem in survivors are penetrating injuries caused by blast-energised debris and fragments of the exploding device. Many of those exposed to a blast will have blunt, blast and thermal injuries in addition to more obvious penetrating wounds. The deafness of blast victims caused by tympanic membrane rupture makes communication difficult and may complicate early assessment. Here, the primary survey and resuscitation phases of a system such as Advanced Trauma and Life Support (ATLS) are particularly apt. The management of penetrating wounds differs little from that of missile wounds referred to earlier. The soft-tissue wounds are usually heavily contaminated and fragments may be driven deeply into adjacent tissue planes opened up by the force of the explosion. In blast injuries, one cannot be sure of complete wound excision

and it is imperative that wounds should be left open at the end of the initial operation and delayed primary closure performed.

Crush injury and syndrome

A crush injury occurs when a body part is subjected to a high degree of force or pressure, usually after being squeezed between two heavy or immobile objects. Damage related to a crush injury includes lacerations, fractures, bleeding, bruising, compartment syndrome and crush syndrome. It can have disastrous consequences on local tissues with extensive destruction and devitalisation (Figure 32.18).

Crush syndrome

The association between crush injury, rhabdomyolysis and acute renal failure was first reported in victims trapped during the 'London Blitz'. It is seen in earthquake and mining accident survivors and in battlefield casualties. Prolonged crushing of muscle leads to a reperfusion injury when the casualty is rescued. This releases myoglobin and vasoactive mediators into the circulation. It also sequesters many litres of fluid, reducing the effective intravascular volume and resulting in renal vasoconstriction and ischaemia. The myoglobinuria leads to renal failure from tubular obstruction (Summary box 32.11).

Summary box 32.11

Crush syndrome

- Arises as a result of reperfusion
- Renal failure from myoglobinuria is a complication
- A late fasciotomy may make things worse not better

The treatment of crushed casualties should begin as soon as they are discovered. Rescuers must be alert to the presence of associated injuries (Figure 32.19). Aggressive volume-loading of patients, preferably before extrication, is the best treatment. After provision of first aid and starting intravenous fluids the patient should be catheterised to measure urine output. In adults, a saline infusion of 1000–1500 mL/hour should be initiated. Alkalinisation of the urine increases the solubility of acid haematin in urine and aids its excretion. This should be continued until myoglobin is no longer detectable in the urine. Mannitol administration can reduce the reperfusion component of this injury. Once a flow of urine is observed, a mannitol–alkaline diuresis of up to 8 litres/day should be maintained, keeping the urinary pH greater than 6.5. A late fasciotomy when it is obvious that the muscles of that compartment must be dead is only likely to cause a massive release of myoglobin, as well as potentially introducing infection into dead tissue. It therefore best not to perform a fasciotomy in cases where entrapment has occurred for over 12 hours.

Intensive care is required with close attention to fluid balance and renal dialysis if required.

Compartment syndrome

A compartment syndrome develops when the pressure within a muscle compartment starts to rise as a result of trauma. This

The London Blitz is the name given to the German air raids on London between September 7, 1940 and May 17, 1941, during which it is estimated that more than 15 000 people were killed. Blitz is short for *Blitzkrieg*, the German for 'lightning war'.

Figure 32.18 Extensive crush injury in a man trapped in a fallen house. The depth to which the soft tissues have been devitalised is seen clearly.

normally only occurs in muscles enclosed in a fascia, such as the muscles of the calf and forearm, and the intrinsic muscles of the hand and foot. It is less likely to occur in an open fracture, as the integrity of the fascial compartment is breached. An overly tight bandage or plaster, haemorrhage from a closed fracture,

Figure 32.19 Rescuers must be prepared for injuries to the spine. Treatment of crush syndrome should start before extrication.

or severe blunt trauma to the muscle leads to a rise in pressure in the compartment until it exceeds venous drainage pressure. The thin-walled veins then collapse under the raised external pressure, and they no longer allow blood to leave the compartment. If the pressure in the compartment is not relieved, it will then rise to mean arterial pressure and perfusion of the muscle will cease. It is important to note that at this stage the distal pulses will still be palpable, though some patients may develop early paraesthesias in the extremity. However, passive stretching of the affected muscle will cause extreme pain and this is diagnostic of the condition. It is at this stage that the situation is still salvageable. Removal of any constricting bandage or plaster, and then if necessary a fasciotomy, will relieve the pressure and perfusion of the muscle will restart. If the condition is left unrelieved then any nerves passing through that compartment will cease to function (distal numbness) and in the final stages even the distal pulses may be lost. The muscle will die and then undergo fibrosis and shortening, producing a Volkmann's ischaemic contracture. Pressure studies are not reliable and if in doubt perform a fasciotomy. Intracompartmental pressure measurements should only be used for diagnosis in the unconscious patient where the classic sign of extreme pain on passive stretching cannot be elicited. Closure of the wound will need to be delayed (Summary box 32.12).

Summary box 32.12**Compartment syndrome**

- Most common in a closed fracture or soft-tissue crush injury
- Pain on passive extension of the muscles is diagnostic
- Intracompartmental pressure studies are not reliable
- If there is any suspicion, then fasciotomy must be performed early

Hypothermia

Hypothermia is a major cause of morbidity and mortality during disasters in cold regions and at high altitudes. It develops rapidly if the individual is immersed in water, covered with wet clothing or exposed to windy conditions. The body responds to cold temperatures by peripheral vasoconstriction as a result of catecholamine release. Shivering is caused by increased tone of the musculature. If the body temperature continues to fall, the body's metabolism declines, and bradycardia with hypoventilation develops. The risk of ventricular fibrillation increases at temperatures below 28°C (82.4°F), and the clotting mechanism is also compromised in hypothermia.

In mild hypothermia, symptoms are vague, including dizziness, lethargy, joint stiffness and nausea. The skin becomes pale and the patient may exhibit confusion and impaired judgement, which progresses to uncoordinated movements and slurred speech. In severe hypothermia, the mental status is further impaired, leading to hallucinations, stupor and coma. Cardiac arrest usually occurs at 20°C (68°F).

The diagnosis is based on a history of exposure and is confirmed by finding a rectal temperatures of 35°C (95°) or less. The principles of treatment in the field include preventing further heat loss, restoring the core temperature and avoiding ventricular fibrillation.

The patient should be moved into dry shelter and wet clothing removed. A fire should be built or a stove lit to increase the temperature of the surroundings. No fluids should be given by mouth and the patient should be warmed passively. This is a safe and simple method of treating mild hypothermia and often the only choice in the field. The patient is covered with blankets or a sleeping bag and rewarmed for 24 hours at a room temperature of 25–33°C (77–91.4°F). Blood volume should be expanded using crystalloid solutions (warmed to 45°C/111°F). In adults, 300–500 mL should be administered rapidly, with the subsequent rate of infusion adjusted according to the blood pressure and urine output.

Severe hypothermia (<28°C/82.4°) should be treated as a life-threatening emergency. If the patient is breathing, humidified oxygen (10 litres/minute) should be administered using a non-rebreathing mask. If the patient is not breathing, ventilation should be initiated with an Ambu® bag connected to a humidified, heated oxygen delivery system. Supplemental oxygen is necessary to prevent hypoxia, reduce the risk of ventricular fibrillation and treat pulmonary oedema (Summary box 32.13).

Even after prolonged cardiac arrest, resuscitation is possible, and patients should not be declared dead until they are first rewarmed. If the patient is still not breathing, endotracheal intubation should be undertaken to maintain the airway. External cardiac compression must be continued in pulseless patients for

Summary box 32.13**Hypothermia**

- Occurs commonly after trauma
- Diagnosed by rectal temperature of 35°C or less
- Rewarming should be passive
- Cardiac arrhythmias and clotting disorders are likely in severe cases
- Continue resuscitation until the patient has been rewarmed

some time. A central line or a venous cut-down should be established to administer warm fluids and for pressure measurements. A Foley catheter is passed to monitor urine output. Cardiac arrhythmias represent an immediate threat to life, but most revert spontaneously with rewarming. At core body temperatures below 30°C (86°F), the heart is usually unresponsive to defibrillation and inotropic agents, so medications are best withheld until rewarming has been achieved.

In severe hypothermia, active rewarming is required, which involves the internal or external addition of heat to the body: externally by heating blankets and warm water immersion; internally by heated humidified inhalation, peritoneal dialysis, haemodialysis or extracorporeal bypass.

Frost bite and immersion injuries (Trench foot)

Frost-bite occurs when a part of the body freezes. The cells are disrupted and the tissue dies. It is in effect a 'cold' burn and can be categorized according to the depth that it affects in the same way as a conventional burn. Other mechanisms are also at play in its causation and include vasoconstriction caused by cold, capillary sludging and reperfusion injury with the release of free radicals which occurs on rewarming the part. It can occur in fingers, toes, cheeks, the tip of the nose and the ears. When frozen, the tissue feels hard and cannot be indented. Immersion injury is a cold injury which does not involve actual freezing of the tissue and is commonly caused by prolonged immersion in cold water (hence 'trench foot'). The patient may also be hypothermic. Warming should be gentle as the heat used may actually cause a burn. Rehydration with warm fluids and use of non-steroidal anti-inflammatory drugs (NSAID), like ibuprofen, are beneficial. Demarcation will occur between dead and viable tissue and at this stage no surgery should be undertaken as there is often considerable deep recovery. The injured area should be kept clean and dry and every effort made to prevent further injury to it, as well as to prevent infection. Definitive surgery to excise dead tissue can be left for many months (Summary box 32.14).

Summary box 32.14**Frostbite**

- Can be superficial or deep like a burn
- Rewarm gently
- Allow demarcation to occur naturally
- Protect against further trauma and infection

HANDING OVER

Follow up and secondary problems

The medical aspect of disaster management does not involve a single short-term effort. It requires a long-term commitment and involvement of various disciplines. Because of the large numbers of casualties, the initial treatment received by patients is directed towards the anatomical restoration of damaged structures. This does not always translate into good functional results. There are therefore numerous patients who will need secondary procedures, such as nerve, tendon and bone grafts, release of contractures and treatment of chronic infection (osteomyelitis). This second wave of patients is encountered three to six months following a major catastrophe and appropriate arrangements should be made to deal with this.

Designated centres

Initially, the casualties seen in major disasters may be scattered among many hospitals. After the first few weeks most of the acute problems have been dealt with and only those patients who require longer-term treatment remain. At this point, it is advisable to designate a particular hospital as a centre for patients with spinal cord injuries and complex limb trauma, who require combined orthopaedic and plastic surgical care along with rehabilitation. It concentrates resources and expertise and makes it easier to follow up these patients.

DISASTER PLANS

Disasters are unforeseen events and planning for them may seem paradoxical. It has, however, been shown that disaster planning not only works but also saves lives. Disaster planning is a wide field but a résumé of the important aspects follows.

Establishment of a national level disaster management organisation

This is the first step in the planning for disasters. Most developed countries already have such an agency, which can formulate policy at the national level and has the infrastructure to react quickly when the need arises.

Anticipating disasters

Areas near active volcanoes and geological fault lines are at risk from seismic disturbances, whereas regions along major rivers are liable to flood. The urban centres of all countries are now potential targets for terrorist attacks. It is important to not only carry out threat assessments, but also, if possible, set up an early warning system (Summary box 32.15).

Summary box 32.15

Disaster planning

- Disaster can be anticipated and should be prepared for
- Evacuation of a whole population may be a best option
- Coordination between military, police, fire, ambulance and medical services is important

Evacuation planning

Evacuation of large population centres as a prelude to or in the wake of an impending disaster is a complex exercise. Yet it may be the most prudent course of action to remove as many people as possible from harm's way. Clear identification of exit routes must be determined and communicated to the populations at risk.

Organisation of emergency services

Emergency services such as the fire brigade, police and ambulance service must have definite roles and areas of responsibility assigned to them to ensure a smooth and coordinated response during a crisis. Members of these teams must be included in the planning phase to ensure that the final plan is practicable and reflects the situation on the ground.

Medical planning

Identification of hospitals able to take large numbers of casualties and the location of areas that can be used for patient holding and triage in case of mass casualties is very important. Hospitals that offer specialised services should be identified and their role during a major crisis made clear. Suitable hospitals in the surrounding areas must be designated as overflow hospitals in the eventuality of a very large volume of patients.

CHAPTER 33

History taking and clinical examination in musculoskeletal disease

LEARNING OBJECTIVES

To understand how to:

- Take a general orthopaedic history

- Perform a systematic examination of each region of the musculoskeletal system

INTRODUCTION

The components of the musculoskeletal system include the bones, joints, ligaments, muscles and tendons as well as the neurological and vascular structures. A simple system allows a concise yet comprehensive history to be taken and a reliable examination to be performed, which will reveal all of the common as well as the more rare but dangerous musculoskeletal problems that are likely to be encountered in clinical practice.

HISTORY

Introduction

- Introduce yourself and check the patient's name and date of birth.
- Explain what you are going to do, obtain verbal consent and ensure that the patient is comfortable.

Take a history

- **Presenting complaint.** Start with an open-ended question. Ask the patient to 'explain what the problem is' in their own words, and ask the patient what their hopes and expectations are from the interview.
- **History of the presenting complaint** ('the three Ws'). When did you first notice the problem? What were you doing when it started? Was it sudden or did it develop gradually?
- **Associated symptoms.** Ask about the following: pain; swelling; instability – 'giving way'; mechanical symptoms (e.g. locking, clicking, clunking); loss of power; altered sensation.
- **Functional impairment.** Ask whether the patient is having difficulties performing activities of daily living: upper limb, e.g. personal hygiene, feeding; lower limb, e.g. putting on shoes and socks, standing, walking and climbing stairs.
- **Past medical history (PMH).** Check for comorbid conditions which may affect the patient's fitness for an anaesthetic, e.g. diabetes, asthma, previous heart attack or stroke. Check for any previous problems with anaesthetics.
- **Past relevant surgical procedures.**
- **Drug history.** Ask about the following in particular:

anticoagulants, steroids, aspirin, immunosuppressants, oral contraceptive pill and hormone replacement therapy.

- **Social history.** Tailor questions to the patient's condition: patient's age; hand dominance; employment status; dependents; alcohol; smoking and hobbies; home help; accommodation – own house, residential or nursing home; use of walking aids; mental test score assessment (Summary box 33.1).

Summary box 33.1

Taking a history

- Introduce yourself and put the patient at ease
- Explain what you are doing and ensure that the patient agrees
- Start with an open question for patient's agenda
- Check for history of presenting complaint and associated symptoms
- Ask about functional impairment
- Check past medical history and relevant surgical history
- Check drug and social history

MUSCULOSKELETAL EXAMINATION

General principles

Apley described a useful and systematic approach to clinical examination. This approach is divided into three parts:

Ernest William Hey Groves, 1872–1944, Professor of Surgery at Bristol. Born in India, he was one of the pioneers of orthopaedic surgery and a great pupil of Sir Robert Jones. Although an orthopaedic surgeon, in his early days, he was consulted by a lady with backache. He correctly diagnosed the cause of the backache to be an ovarian cyst. The lady insisted that Hey Groves should remove the cyst himself. With the help of his wife, a nurse, he successfully removed the cyst in an improvised room at his home. He was the founder member of the *British Journal of Surgery*.

Alan Graham Apley, 1914–1996, Director of Orthopaedic Surgery, St Thomas' Hospital, London, UK. As a consultant also at Rowley Bristow Orthopaedic Hospital, he conducted the most popular orthopaedic postgraduate course for the FRCS examination in Pyrford, Surrey, which became internationally known as the 'Pyrford Orthopaedic Course'.

- 1 look;
- 2 feel;
- 3 move.

Look

The inspection begins as soon as you enter the examination room. Look for any walking aids. Remember to look at the whole patient and not just at the joint of interest. For example:

- look at the hands for rheumatoid arthritis;
- look at the eyes for Horner's syndrome;
- look for any obvious upper or lower limb or spinal deformity.

Gait

The gait cycle is all of the activity between the initial contact of the foot with the ground and the succeeding initial contact of the same limb. There are two main stages: the stance phase (60 per cent) and the swing phase (40 per cent). Ask the patient to stand, and inspect from the front, side and back. Then, ask the patient to walk using any walking aids. Some of the types of limp that might be present are described in Table 33.1.

Focused inspection

Adequately expose the joint above and below. Expose the opposite limb for comparison. Make sure that the patient is comfortable. It may be easier for you and the patient if they remain standing for the first part of the examination. When a couch is used, make sure that it is in the centre of the room (not against the wall) so that you can work on both sides of the patient.

Remember that all joints are covered by an envelope of soft tissues and skin. Look at the skin for:

- surgical scars;
- bruising (may indicate recent injury or a bleeding disorder);
- erythema (e.g. cellulitis);
- ulcers (e.g. arterial, vascular or neuropathic);
- rashes;
- sinuses (e.g. secondary to osteomyelitis);

Friedrich Trendelenburg, 1844–1924, Professor of Surgery successively at Rostock (1875–1882), Bonn (1882–1895), Leipzig (1895–1911), Germany. The Trendelenburg position was first described in 1885.

- hair loss and the presence or absence of sweating;
- pigmentations or raised lesion (e.g. café-au-lait spots or neurofibromas).

Look at the soft tissues for:

- swelling (e.g. may indicate a joint effusion);
- lumps (consider which tissue layer they are arising from);
- muscle wasting (e.g. may be secondary to disuse atrophy, neuropathy);
- muscle fasciculation (lower motor neurone pathology).

Look at the bones for:

- abnormal limb alignment – comparison with the other side may be helpful;
- deformity.

Feel

Ask the patient if they have any areas of tenderness. Ensure that you do not cause the patient pain – watch their face as you feel. It may be easier (especially with children) to feel the normal side first.

Skin

The aim of sensory testing is to establish a pattern of sensory loss. Look for a dermatomal (may indicate spinal root or peripheral nerve pathology) or glove and stocking distribution (may indicate a neuropathy, e.g. diabetes).

Perform a screening test by lightly stroking both limbs. Record whether the patient feels a difference. If none is noticed there is no need to spend more time on the neurological examination. If there is a difference, then a full neurological examination should now be performed.

Soft tissues

- **Tenderness:** Try to determine the actual anatomical structure from which the pain arises (e.g. subcutaneous fat, bursae, nerves, arteries).
- **Lumps and effusions:** Determine the characteristics of any lump or effusion using Table 33.2 as a guide.
- **Pulses:** Palpate the distal pulses (or capillary return) of the limb. Recording distal neurovascular status both before and after surgery is important. Absence of distal pulses is an

Table 33.1 Types of limp.

Cause	Pathogenesis	Presentation
L ong	Osteoarthritis (in other leg)	Head dips. Cadence dash/dash
I ncoordinated	Cerebral palsy	Head moves everywhere. No regular cadence
M uscle weakness	Osteoarthritis hip	Head moves from side to side (windscreen wiper)
P ain	Osteoarthritis hip	Head dips. Cadence dot/dash
S tiff	Arthrodesis hip	Head rocks too and fro
Limp	Pathology	
Antalgic	Hip joint arthritis	
Trendelenburg	Weakness of hip abductors	
High-stepping gait	Foot drop secondary to common peroneal nerve palsy	
Spastic	Cerebral palsy	
Ataxic	Cerebellar pathology	

Johann Friedrich Horner, 1831–1886, Professor of Ophthalmology, Zurich, Switzerland, described this syndrome in 1869.

Table 33.2 Swelling – an acronym for history and examination of a lump.

S tart	Did it appear after trauma or gradually on its own?
W here	Anatomical site and layer (skin, fat, muscle); does it move in relation to these?
E xternal features	Size, surface and definition of margins
L ymph nodes	Are the local ones enlarged?
L iquid	Is it fluctuant? Can it be transilluminated?
I nternal features	Is it hard? Is it tender?
N oise	Is there a thrill? Is there a bruit?
G eneral	Examination of the whole patient for general lumps

absolute contraindication to elective surgery in that limb.
Acute loss of circulation to a limb is a surgical emergency.

Bone

Palpate the contours of the joint and assess for tenderness. For superficial joints, such as the knee, the joint line can be felt and checked for lumps and tenderness.

Move

There are three stages to assessing movement. The words used to describe a particular movement are shown in Table 33.3.

Table 33.3 Terminology used to describe the direction of movement.

Flexion	Forward or anterior movement of the trunk or limb
Lateral flexion	Bending of the forward-facing head and trunk to either side
Extension	Backward or posterior movement
Abduction	A movement away from the midline of the body
Adduction	A movement towards the midline of the body
Internal rotation	Rotation towards the midline of the body
External rotation	Rotation away from the midline
Supination	Movement of the forearm so that the palm faces anteriorly
Pronation	Movement of the forearm so that the palm faces posteriorly
Circumduction	A combination of flexion, abduction, extension and adduction without rotation
Inversion	Movement of the foot that directs the sole of the foot medially
Eversion	Movement of the foot that directs the sole of the foot laterally
Retraction	Backwards movement of the head, jaw or shoulders

- **Active.** Ask the patient to move the joint within the limits of their pain.
- **Passive.** Move the joint yourself. Record the range of movement in 'degrees' (a goniometer may be helpful). Comparison of active and passive range allows the three causes of loss of range of movement to be distinguished. In limitation caused by pain or stiffness the ranges are the same but one is painful. In weakness passive range is greater than active.
- **Stability.** Stability has a static and a dynamic component: static tests assess the integrity of the ligaments and joint (bone) surfaces; dynamic tests assess the integrity and functions of the muscles and tendons. Ask the patient to actively move the joint through its range of motion while you try to stop the movement. Record power using the Medical Research Council (MRC) grading system as illustrated in Table 33.4. Consider the muscles that drive each movement, the peripheral nerves that supply them and the nerve root values (Table 33.5).

Table 33.4 The Medical Research Council grading system of muscle power.

Grade	Description
0	No movement
1	Flicker of movement
2	Active movement with gravity elimination
3	Active movement against gravity
4	Active movement against resistance but power less than full
5	Normal power

In the following sections, in addition to the approach of 'Look, Feel, Move', we have included details of special tests for each joint as well as neurological examination of the limb. The peripheral nerve examination comprises sensory and motor testing, reflexes, tone and coordination and proprioception (Summary box 33.2).

Summary box 33.2

Musculoskeletal examination

- Introduce yourself and put the patient at ease
- Assess the gait
- Look
- Feel
- Move
- Special tests
- Neurological examination
- Pulses

CLINICAL EXAMINATION OF THE SPINE

The spinal column consists of 33 vertebrae with 23 intervertebral discs. This is supported by numerous ligaments and paraspinal muscles.

Table 33.5 Peripheral nerves.

Root level	Sensation	Motor	Reflex
C5	Lateral upper arm	Deltoid	Biceps
C6	Lateral forearm	Wrist extension	Brachioradialis
C7	Middle finger	Triceps	Triceps
C8	Little finger	Finger flexors	—
T1	Medial forearm	Interossei	—
L1	Anterior thigh	Psoas	—
L2	Anterior thigh/groin	Quadriceps	—
L3	Anterior and lateral thigh	Quadriceps	—
L4	Medial leg and foot	Tibialis anterior	Knee jerk
L5	Lateral leg and first dorsal web space	Extensor hallucis longus	—
S1	Lateral and plantar foot	Gastrocnemius/perineals	Achilles
S2–S4	Perianal	Bladder and foot intrinsic	—

When observed from the front (coronal plane) with the patient standing and the hips and knees fully extended, the head should be centred over the sacrum. A 'plumb line' dropped from the spinous process of C7 should fall through the gluteal crease (Figure 33.1). If it falls to either side of the cleft, lateral tilt of the spine is present. The ear, shoulder and greater trochanter of the hip should lie in the same vertical plane. When the patient is observed from the side, assess the four physiological sagittal plane curves (cervical and lumbar lordosis, and the thoracic and sacral kyphosis) (Figure 33.2).

Cervical spine

Look

Ensure that the shoulders, back muscles and scapulae can be seen. Look for muscle wasting and asymmetry of the neck creases and check that the shoulders are level and that there is a normal cervical lordosis (range 20–40°).

Feel

Stand behind the patient and support the patient's chin:

- **Soft tissues.** Feel for spasm of the paraspinal muscles.
- **Bone.** Palpate the spinous processes (tenderness and alignment); the spinous processes of C7 (vertebra prominens) and T1 are usually large and are easily palpable at the base of the neck.

Move

Motion occurs in three planes: flexion/extension, bending and rotation (Figure 33.3):

- **Flexion (45°)/extension (55°).** Ask the patient to bend their neck forwards – place the chin on the chest. Measure the distance from the chin to the sternum. Ask the patient to extend their neck by looking up at the ceiling.
- **Right/left bending (40°).** Ask the patient to lay their ear on their ipsilateral shoulder.

- **Right/left rotation (70°).** Ask the patient to look over each shoulder while not moving the chest wall.

Neurological

Focus your examination on the C5 to T1 nerve roots. These supply the upper extremities (Figure 33.4).

Thoracic spine

Pathology commonly presents with pain and deformity. The thoracic spine is normally convex with a gentle kyphosis (normal range 20–45°).

Figure 33.1 Plumb line.

Figure 33.2 Standing sagittal profile of cervical and lumbar lordosis (a), and thoracic (b) and sacral (c) kyphosis.

Figure 33.3 Cervical spine flexion/extension (a and b), rotation (c) and bending (d).

Figure 33.4 Spurling's test for cervical spine nerve root entrapment. Extend the cervical spine and rotate the head to each shoulder in turn. The presence of a shooting pain down the arm may indicate cervical nerve root compression.

Figure 33.5 Forward bending test.

Look

Ensure that the front and the back from the neck to the gluteal cleft can be visualised. Note skin markings (e.g. café-au-lait spots, hairy patches). These may suggest occult neurology or bony pathology.

- **Front:** Check for asymmetry of the shoulder and rib cage suggesting scoliosis.
- **Back:** Look for a difference in the height of the iliac crests (pelvic tilt). Assess for coronal plane deformity, such as scoliosis (lateral curvature of the thoracic spine with rotation). A rib hump suggesting a structural scoliosis may be visible.
- **Side:** Assess for sagittal plane deformity, such as an increased kyphosis.

Feel

Palpate with one hand supporting the patient's pelvis.

Move

Range of motion is limited in the thoracic spine:

- **Forward bending test** (Figure 33.5). Ask the patient to bend forwards to touch their toes:
 - structural scoliosis: a rib hump will increase in size (bulge posteriorly on the thoracic convex side) as the patient bends forwards; this is diagnostic of idiopathic thoracic scoliosis (rotatory deformity);
 - functional scoliosis: the spine straightens as the patient bends forwards and no rib hump is visible; this flexible deformity is secondary to other abnormalities such as abnormal leg lengths and muscle spasm in the lumbar region.

- **Lateral bending** can be used to assess the flexibility of a scoliosis. Radiographs are taken in this position to supplement the assessment.

Lumbar spine

Examination should include the pelvis, hips, lower limbs, gait and peripheral vascular system as well as the lumbar region. Irritation of nerves in the lumbar spine can mimic problems in the lower limb. Always consider referred pain.

Look

- **Back:** Check the skin at the base of the spine for hairy tufts and dimples (underlying spina bifida). Prominence of the spinal muscles on one side may be the result of muscle spasm secondary to pain.
- **Side:** The lumbar spine has a smooth concavity known as the lumbar lordosis (normal range is 40–60°). Muscle spasm is a cause of loss of the normal lordosis.

Feel

Feel for any 'step-off' in the spinous processes. This may indicate forward slippage of one of the vertebrae on another.

Move

Movement occurs in flexion, extension, lateral bending and rotation (Figure 33.6). Record the motion in each plane in degrees. Remember that a significant portion of lumbar flexion is achieved through the hip joint.

- **Forward flexion** is a measure of lumbar flexibility. The skin of the lumbar spine stretches as the patient bends forwards.

Figure 33.6 Lumbar flexion/extension, lateral bending (a) and rotation (b).

To measure flexion, place the tip of your thumb over the T12–L1 junction and the tip of your index finger of the same hand over the lumbosacral junction. Ask the patient to bend forwards and touch the toes (normal range 40–60°). Measure the distance by which your thumb and the tip of your index finger separate.

- **Lateral bending.** Ask the patient to slide their right hand down the outer side of their right leg and then their left hand down the outside of their left leg. Note the distance that each hand moves down that side of the thigh.
- **Rotation.** Stand behind the patient and hold their pelvis still with both hands. Ask the patient to twist around and look over their shoulder. Note the angle that the shoulder girdle forms with the pelvis (range 3–18°).

Special tests

- **Lasègue's straight leg raise test** (Figure 33.7). This test increases tension along the sciatic nerve (L5 and S1 nerve roots). With the patient supine, elevate the leg with the knee bent to check pain-free movement of the hip. Then, straighten the knee and note the angle which the hamstrings allow the hip to flex. Finally, allow the hip to extend until tension is removed from the hamstring muscles and then the ankle is dorsiflexed firmly, tugging on the sciatic nerve. If the patient experiences pain running down the leg, then the test is positive.
- **Contralateral stretch test.** Elevate the asymptomatic leg; if pain is reproduced in the other leg the test is considered positive (Summary box 33.3).

Charles Ernest Lasègue, 1816–1863, Professor of Medicine, The University of Paris, and Physician, La Salpêtrière, Paris, France. This test was described by Lasègue's student, who named it after his teacher.

Summary box 33.3

Spine examination

Inspection of the standing patient

- From the front and back (coronal plane)
- From the side (sagittal plane)

Palpation

- Palpation of the posterior bony elements and the paraspinal muscles

Move

- Assess flexion, extension, lateral rotation and bending

Neurological

- Assess sensation, tone, power, reflexes, proprioception and coordination

Special tests

- Spurling's test
- Forward bending test
- Lasègue's straight leg test
- Contralateral stretch test

CLINICAL EXAMINATION OF THE HAND AND WRIST

The hand and wrist should be thought of as one functional unit. The muscles may be divided into extrinsic (the muscle bellies in the forearm) and intrinsic (origins and insertions within the hand alone). The 'flexors' (volar side) flex the wrist and fingers and the 'extensors' (dorsal surface) extend the digits and fingers.

Look

Inspect the posture of both hands. A nerve lesion will produce a specific resting position (e.g. an ulnar nerve lesion will produce clawing of the little and ring fingers).

Figure 33.7 Lasègue's straight leg test.

Table 33.6 Patterns of muscle wasting in the hand.

Thenar wasting	Median nerve palsy (C8)
Hypothenar wasting	Ulnar nerve palsy (T1)
Intrinsic wasting	Ulnar nerve palsy (T1)

Figure 33.8 Thenar (a) and hypothenar (b) wasting.

- **Skin.** Assess for scars, discolouration (café-au-lait spots, erythema) and loss of hair. The nails may reveal systemic disease (e.g. psoriatic pitting). Look for tight bands in the palm (Dupuytren's contracture). Loss of sweating is seen in complex regional pain syndrome.
- **Soft tissue.** Centrally located swellings at the wrist may indicate a ganglion arising from the wrist joint itself; de Quervain's tenosynovitis may present with a swelling around the radial styloid.
- Check for thenar, hypothenar (Figure 33.8) and intrinsic muscle wasting. To assess thenar eminence wasting, place the hands side by side with the thumbs upwards and look down and compare the thenar regions. Patterns of muscle wasting are shown in Table 33.6.
- **Bones.** Look for bony deformity (dinner fork deformity, Colles' fracture). Typical bony deformities are described in Table 33.7.

Feel

- **Skin.** If there is any question of abnormal sensation on a simple stroke test comparing both sides, proceed to the two-point discrimination test using the sharp ends of a paper clip. Record the minimum distance between the tips of the paper clip at which the patient is able to recognise two points. Table 33.8 describes the anatomical region supplied by the median, ulnar and radial nerves.
- **Pen sliding test.** To assess the absence or presence of sweating, slide a pen along the radial border of the index finger. If the pen slides smoothly, this may indicate loss of sweating.
- **Soft tissue:**
 - blood vessels: check the radial and ulnar artery pulses; assess the capillary refill time, which is normally less than 2 seconds; Allen's test should also be performed before surgery (Table 33.9 and Figure 33.9);

Baron Guillaume Dupuytren, 1777–1835, Surgeon Hôtel Dieu, Paris, France, described the condition in 1831.
Friedrich Joseph de Quervain, 1868–1940, Professor of Surgery, Berne, Switzerland, described this form of tenosynovitis in 1895.
William Heberden (Snr), 1710–1801, a physician who practised first in Cambridge and later in London, UK.
Charles Jacques Bouchard, 1837–1915, physician, Dean of the Faculty of Medicine, Paris, France.
Boutonnière is French for 'button-hole'.

Table 33.7 Bony deformities of the hand.

Anatomical site	Name	Association
Distal interphalangeal joint (DIPJ)	Heberden's nodes	Osteoarthritis
Proximal interphalangeal joint (PIPJ)	Bouchard's node	Osteoarthritis
Hyperextension of the metacarpophalangeal joint (MCPJ), flexion of the PIPJ and hyperextension of the DIPJ	Boutonnière deformity	Rheumatoid arthritis
Hyperextension of the MCPJ and PIPJ and flexion of the DIPJ	Swan neck deformity	Rheumatoid arthritis
Flexion of the MCPJ with hyperextension of the interphalangeal joint	Z deformity of the thumb	Rheumatoid arthritis
Subluxation of the MCPJ	Ulnar drift	Rheumatoid arthritis

Table 33.8 Sensory distribution of the nerve supply to the hand.

Nerve	Sensory distribution
Ulnar	Little finger and ulnar half of the ring finger
Median	Thumb, index, middle and radial half of the ring finger
Radial	Base of the thumb on the dorsum of the hand

- **nerves:** compressive neuropathies are most commonly seen affecting the median nerve (see Tinel's (Figure 33.10a) and Phalen's (Figure 33.10b) test in Table 33.9);
- **palmar fascia:** feel for palmar thickening and skin pits; long finger-like structures (cords), most commonly affecting the ring and little fingers, are suggestive of Dupuytren's disease.
- **Bones.** Palpate from the radial to the ulnar side of the wrist joint. In the trauma setting, palpate the anatomical snuff box (Figure 33.11). A fracture of the scaphoid may cause tenderness.

The scaphoid tubercle, pisiform and the hook of hamate are all palpable on the volar aspect of the wrist.

Move

The wrist can be moved into flexion and extension, and ulnar and radial deviation.

- **Wrist.** Extension is tested by asking the patient to push the hands together into a 'prayer' position (Figure 33.12a). If there is loss of extension, the palms will not meet and/or one forearm will be dropped. Palmar flexion is tested in a similar fashion but with the hands pointing down and the back of the hands in contact (Figure 33.12b). Ulnar and radial deviation are tested by taking the patient's hand in your own and moving the hand into these directions.
- **Hand.** A general screening assessment is to ask the patient to roll up their fingers from full extension to full flexion. This will reveal a trigger finger.

Extensors and flexors

Asking the patient to grip two of your fingers in their fist tests the power of the extensors of the wrist (radial nerve) because they are needed to brace the wrist. It also tests the power of the flexors in the forearm (median nerve). Asking the patient then to extend and spread their fingers apart against resistance tests the intrinsic muscles of the hand (mainly the ulnar nerve).

George S Phalen, contemporary, orthopaedic surgeon and Chief of Hand Surgery, The Cleveland Clinic, Cleveland, OH, USA. He helped to establish the American Society for Surgery of the Hand.

Table 33.9 Special hand tests.

Test	Technique	Significance
Allen's test	Elevate the hand and apply digital pressure on the radial and ulnar arteries to occlude them. Ask the patient to make a fist several times. The tips of the finger should go pale. Release each artery in turn and observe the return of colour	Tests the adequacy of the blood supply to the hand from the radial and ulnar arteries and the arcade between them
Tinel's test	Tap over the nerve of interest. Tingling may indicate nerve compression	Identifies compression of a peripheral nerve
Phalen's test	Place the wrist in maximum flexion with the elbows extended	Compression of the median nerve causes paraesthesia
Froment's sign	Ask the patient to grip a sheet of paper between the index finger and thumb of both hands. Grip the paper yourself similarly. Ask the patient to resist as you attempt to pull the paper away	A positive test indicated by flexion of the thumb interphalangeal joint suggests weakness of the adductor pollicis muscle supplied by the ulnar nerve. Recruitment of the median nerve-innervated flexor pollicis brevis explains the thumb posture

Figure 33.10 (a) Tinel's test; (b) Phalen's test.

Figure 33.11 Palpating the anatomical snuff box between the tendons of extensor pollicis longus and abductor pollicis brevis.

Figure 33.9 (a–c) Performing Allen's test.

Finger flexors

- **Superficialis tendon test.** The flexor digitorum profundus (FDP) usually has one muscle belly from which tendons to all of the fingers arise. The FDP can be immobilised by holding all of the fingers (except the one being examined) in extension; this allows the superficialis tendon to be tested in isolation. If the test finger is able to flex, despite profundus being immobilised, then the superficialis tendon to that finger is working. Repeat the test for the other fingers individually (Figure 33.13).

Other muscles

- **Thenar eminence:**
 - The abductor pollicis brevis, opponens pollicis and flexor pollicis brevis can be tested together by opposing the thumb to the little finger.
 - The flexor pollicis longus which is supplied by the anterior interosseus nerve (branch of the median nerve) can be tested by asking the patient to bring the tips of the thumb and index finger together (the 'OK' sign – Figure 33.14).
 - The integrity of the extensor pollicis longus tendon is tested by asking the patient to lift the thumb off a table with the palm flat on the table (Figure 33.15).
- **Adductor pollicis:** Test using Froment's sign (see Table 33.9 and Figure 33.16).

Thumb abductor pollicis brevis

This muscle is supplied by the median nerve. With the hand lying flat on a table with the palm facing upwards, ask the patient to raise the thumb towards the ceiling. Ask the patient to resist as you push the thumb back towards the palm (Figure 33.17) (Summary box 33.4).

Figure 33.13 Testing the (a) flexor digitorum superficialis; (b) flexor digitorum profundus.

Figure 33.12 Testing the range of (a) wrist extension; (b) wrist flexion.

Summary box 33.4

Hand and wrist examination

Inspection of the standing patient

- Dorsum and palm – asymmetry, deformity, muscle wasting

Inspection of the supine patient

- Skin, scars, soft tissues
- Palpation of bony structures and joints of the hand

Movements

- Wrist – flexion and extension, ulnar and radial deviation
- Hand – thumb movements, metatarsophalangeal joints and small joints of the hand

Special tests

- Allen's test
- Tinel's and Phalen's test for the median nerve
- Froment's sign
- Finkelstein's test

Figure 33.14 Test for flexor pollicis longus supplied by the anterior interosseus nerve.

Figure 33.15 Testing the integrity of extensor pollicis longus.

Figure 33.16 Froment's sign; the arrow illustrates the flexed posture of the thumb interphalangeal joint, indicating weakness of the ulnar nerve-innervated adductor pollicis muscle.

Figure 33.17 Testing the power of the abductor pollicis brevis supplied by the median nerve.

CLINICAL EXAMINATION OF THE ELBOW

The elbow is a hinge joint formed by the articulation of the ulna and radius with the humerus.

Look

- **Skin.** Check the extensor surface for signs of psoriasis.
- **Soft tissues.** Look for any swellings, e.g. olecranon bursa, rheumatoid nodules, gouty tophi.
- **Muscle wasting.** Examine the biceps and triceps muscle bulk. Note that compression of the ulnar nerve at the elbow leads to wasting distally in the hypothenar eminence and intrinsic muscles of the hand – assess the hand for the presence of clawing and wasting.
- **Bone.** With the elbow in extension, look at the axis between the upper arm and forearm. There is a physiological valgus ('carrying angle') of 9–14° (2–3° greater in women) (Figure 33.18). This angle allows the elbow to be tucked into the waist depression above the iliac crest:
 - cubitus varus (gun-stock deformity): the carrying angle is reversed, secondary to a malunited supracondylar fracture;

- cubitus valgus: the carrying angle is increased, caused by malunion of a distal humeral fracture;
- there is normally a physiological hyperextension of the elbow (5°).

Feel

- **Soft tissues.** An effusion may be elicited by performing a crossfluctuation test. The ulnar nerve can be rolled under

Figure 33.18 Carrying angle of the elbow illustrating the normal cubitus valgus.

your fingers placed between the medial epicondyle and the olecranon. Test the distal sensation in the hand (especially in the distribution of the ulna nerve) and assess the vascular status.

- **Bones.** The three palpation landmarks are the medial and lateral epicondyles and the apex of the olecranon. These form an equilateral triangle when the elbow is flexed to 90°. The radial head is palpated with the examiner's thumb while the other hand pronates and supinates the forearm. On the medial side, palpate the medial epicondyle. Posteriorly, palpate the olecranon fossa.

Move

- **Flexion–extension.** The normal range is from -5° (slight hyperextension) to 150° . Ask the patient to bend the elbow from the fully straight position (Figure 33.19).
- **Pronation and supination.** With the elbows at 90° and the palms facing upwards (full supination), ask the patient to turn the forearm so that the dorsum of the hand faces upwards (full pronation) (Figure 33.20). The normal values are 70° pronation and 90° supination.

Special tests and diagnoses

Tennis elbow and golfer's elbow

These are inflammatory processes of the tendons that attach the large muscle mass of the forearm to the lateral or medial epicondyle.

- **Medial epicondylitis (synonym = golfer's elbow).** The medial epicondyle is the common origin of the forearm flexors and the pronator muscle. Palpate the medial epicondyle for tenderness. The diagnostic test is resisted wrist flexion, which reproduces the pain over the medial epicondyle.
- **Lateral epicondylitis (synonym = tennis elbow).** The lateral epicondyle is the common origin of the forearm extensors. Palpate for tenderness – usually just distal (5–10 mm) to the

Figure 33.20 Testing forearm rotation: (a) mid-prone position; (b) full supination; (c) full pronation.

epicondyle near the origin of the extensor carpi radialis brevis muscle. Wrist extension against resistance with the elbow extended should provoke the patient's symptoms (Summary box 33.5).

Figure 33.19 (a) Elbow flexion; (b) elbow extension.

Summary box 33.5

Elbow examination

Inspection of the standing patient

- Front – asymmetry, carrying angle, deformity
- Back – olecranon fossa

Inspection of the supine patient

- Skin, scars, soft tissues, deformity
- Palpation of bony structures

Movements

- Flexion and extension, pronation and supination

Special tests

- Tennis and golfer's elbow
- Stability testing
- Ulnar nerve compression
- Biceps tendon power

CLINICAL EXAMINATION OF THE SHOULDER

Pain arising from the shoulder joint may be felt anterolaterally. Referred pain may present from the cervical spine, heart, mediastinum and the diaphragm.

Look

Assess the attitude of the limb.

- **Skin.** Check for surgical scars. An anterior scar is used for the deltopectoral approach. At the side, the deltoid splitting approach and lateral arthroscopic portals may be seen. Posteriorly, arthroscopic portal sites can be seen.
- **Soft tissues.** Wasting of the deltoid muscle is commonly seen after shoulder dislocation when there is a temporary loss of function of the axillary nerve that supplies it.
- **The rotator cuff** comprises four muscles: supraspinatus, infraspinatus, subscapularis and teres minor. Wasting of these muscles may occur following a rotator cuff injury.
- **Bone.** Look for any obvious deformity or prominence. A fracture of the middle third clavicle is the most common cause. A dislocation may be suspected by a loss of normal shoulder contour. The more common anterior dislocation often presents with an anterior bulge and a squared-off shoulder.

Feel

Generalised pain in the shoulder may arise from the neck or the shoulder joint itself. More localised pain is often indicative of acromioclavicular joint pathology.

- **Skin.** Test sensation in the upper part of the lateral aspect of the arm ('regimental badge area') (Figure 33.21). Loss may indicate damage to the axillary nerve (following shoulder dislocation).
- **Bones.** Palpate the acromioclavicular and sternoclavicular joints and the clavicle.

Move

Differentiate between movements of the shoulder joint and scapulothoracic movement of the scapula on the chest wall. Patients with a painful shoulder will commonly move from the scapulothoracic joint. Stabilise the scapula by placing the thumb over the coracoid process and the fingers of the same hand over the spine of the scapula. Start in the 'neutral position' with the arms by the side, elbows extended and the palm facing forwards. Note any pain throughout the range of movement (Figure 33.22).

- **Forward flexion.** Ask the patient to raise their hands in front to touch the ceiling while keeping the elbows extended (0–180°).
- **Extension.** Ask the patient to extend both arms behind (0–30°).
- **Abduction.** Shoulder abduction involves the glenohumeral joint and scapulothoracic movement. The first 60° of movement is mainly at the glenohumeral joint. Beyond this the scapula begins to rotate on the thorax and final movements are almost entirely scapulothoracic. Raise the arms sideways until the fingers point to the ceiling (180°).
- **Adduction.** Ask the patient to touch their other shoulder tip.
- **Internal rotation.** Ask the patient to touch their back with the dorsum of the hand and to raise their hand up the back as high as possible (normal range is thoracic spine level T7–9).
- **External rotation.** With the arms by the sides, bend the elbow to 90° and rotate the forearms to the mid-prone position. Ask the patient to separate their hands as much as possible (0–40°).

Figure 33.21 The area of skin supplied by the axillary nerve – the 'regimental badge area'.

Special tests and diagnoses

Impingement syndrome

This is impairment of rotator cuff function within the subacromial bursa. It may lead to inflammation (tendinitis) or a partial- or full-thickness tear. Impingement is characterised by pain and weakness on abduction and internal rotation.

- **Painful arc test** (Figure 33.23). Ask the patient to abduct their arms from their sides. The presence of pain from 60° to 120° is positive.
- **Jobe's test (empty can)** (Figure 33.24). Ask the patient to abduct the arm to 90° elevation in the scapula plane with full internal rotation (empty can position). Ask the patient to resist downward pressure. The presence of pain is a positive test.

Shoulder instability

Instability may be defined as a shoulder that slips in and out of joint (dislocation) more than once or twice, or frequently slips partially out of joint and then returns on its own. Instability can be anterior, posterior, inferior or multidirectional.

- **Apprehension test** (Figure 33.25). With the patient supine or standing, flex the elbow to 90° and abduct the shoulder to 90°. Now externally rotate the shoulder. Apprehension indicates anterior instability (Summary box 33.6).

CLINICAL EXAMINATION OF THE HIP JOINT

The hip is a synovium-lined ball and socket joint. Typical clinical diseases of the hip that may be encountered in children and adults are shown in Table 33.10.

A patient complaining of hip pain should undergo a careful examination of the spine, abdomen, pelvis, groin and thigh. In addition, consider a gynaecological examination in women.

(a)

(b)

(c)

(d)

(e)

Figure 33.22 Movements of the shoulder: (a) forward flexion; (b) extension; (c) adduction; (d) internal rotation; (e) external rotation.

Look

With the patient standing, look at the front, side and back of the hip. Look around the room for walking aids and heel raises in the shoes.

- **Skin.** Look for scars and sinuses.
- **Soft tissues.** Muscle wasting may be present as a consequence of hip arthritis or primary muscle or neurological disease.

- **Bone.** Look at the posture of the limb and assess for adduction deformity; fixed adduction may be present in severe osteoarthritis and cerebral palsy, and makes the leg appear short because the pelvis is tilted (apparent shortening).

Feel

- **Soft tissues.** Tenderness overlying the greater trochanter may suggest trochanteric bursitis or an abductor enthesopathy.

(a)

(b)

(c)

Figure 33.23 (a–c) Painful arc test for rotator cuff impingement.

Summary box 33.6

Shoulder examination

Inspection of the standing patient

- Front – asymmetry, deformity
- Side – muscle wasting
- Back – muscle wasting, scapula

Inspection of the supine patient

- Skin, scars, soft tissues, deformity
- Palpation of shoulder girdle (sternum to scapula)

Movements

- Flexion and extension, abduction and adduction, internal and external rotation

Special tests

- Impingement syndrome – painful arc, Jobe's test, Hawkins' test
- Shoulder instability – apprehension, relocation test, sulcus sign
- Rotator cuff assessment
- Acromioclavicular joint pathology
- Frozen shoulder versus glenohumeral osteoarthritis

Figure 33.24 Jobe's test for rotator cuff impingement.

Move

The hip joint can be moved into flexion, extension, abduction and adduction and internal and external rotation (Figure 33.26). True hip movement ends when the pelvis begins to move. To detect true hip movement, simultaneously place a finger/hand on the anterior superior iliac spine (ASIS) contralateral to the hip being examined. Remember to compare both sides.

Figure 33.25 Anterior apprehension test for anterior shoulder instability.

Passive movement

Hip flexion and extension (120–0°)

The patient is asked to lie on their back and then roll themselves into a ball, flexing the hips and the spine fully. A comparison of the flexion of the two hips can be made in this position. The patient is then asked to hold onto the knee of the 'bad' leg with both hands (thereby fixing the pelvis in flexion) and the other leg is allowed to extend down onto the couch. A note is made of any fixed flexion deformity (inability of the thigh to come down onto the couch). This 'good' hip is then returned to full flexion and the patient grasps that knee while dropping the other 'bad' hip into extension. This modified Thomas's test is the most comfortable and accurate way of measuring flexion and extension of the hip, minimising movement of the painful hip (Figure 33.27).

Rotation

- **Internal rotation (45°).** With the hip flexed to 45° and the knee in 90° of flexion, hold the front of the knee with one hand and the foot with the other. Internally rotate the hip (the foot goes outwards), then externally rotate the hip (the foot goes in). The angle that the tibia makes with the vertical indicates the range of movement. Pain at the extremes of movement suggest inflammation in the hip.
- **Abduction (40°).** The hip should be abducted by moving the leg away from the midline with the other hand on the patient's pelvis to detect any tilt in the pelvis.

Special tests

- **Trendelenburg test** (Figure 33.28). Face the patient and ask them to place their hands on the palm of your hands for support. Then ask them to stand first on one leg, then the other. Increased pressure from the opposite hand as they take weight through the weak hip indicates a positive Trendelenburg test.
- **Leg length discrepancy (LLD).** The inequality may be in the hip joint, femur, tibia, ankle or foot or a combination of these. The pathology may be from the bone being too short or too long (Summary box 33.7). When assessing LLD, square the pelvis. If that is not possible then place both legs in the same position. For example, if there is an adduction deformity present in the affected leg, place the good leg in the same degree of adduction. LLD can be caused by a real

Hugh Owen Thomas, 1834–1891, general practitioner, Liverpool, UK. He is regarded as the founder of orthopaedic surgery although never holding a hospital appointment, preferring to treat patients in their own homes. He introduced the Thomas splint in 1875.

Table 33.10 Common clinical diseases of the hip in children and adults.

Children	Adults
Developmental dysplasia of the hip	Primary osteoarthritis
Transient synovitis of the hip	Secondary osteoarthritis
Perthe's disease	Inflammatory arthritis
Septic arthritis and osteomyelitis	Avascular necrosis
Slipped capital femoral epiphysis	Labral tears
Juvenile idiopathic arthritis	Referred pain

difference in the leg lengths (the bones are different lengths) or by a deformity that makes the leg appear short because the pelvis must be tilted to get the leg onto the ground. The first is called 'real' LLD. The second is called 'apparent' LLD. Both are real to the patient but the cause and therefore the treatment are different. The LLD apparent to the patient can also be measured using wooden blocks placed under the patient's 'short' leg until the patient feels level.

Summary box 33.7

Common causes of limb length inequality in the hip

- Osteoarthritis
- Hip fracture
- Hip dislocation
- Hip dysplasia
- Avascular necrosis
- Fixed flexion deformity

- **Gait.** Hip disease can present with an altered gait pattern. The common types of abnormal gait are described in Table 33.11 (Summary box 33.8).

Table 33.11 Common limps observed in hip disease.

Gait pattern	Description
Weak: Trendelenburg	May lead to pelvic sway or tilt. The patient swings the body over the weak hip to stay in balance when it is weight bearing
Painful: antalgic	The rhythm is dot-dash, with a short period spent on the painful limb
Unbalanced: broad-based	May be caused by ataxia, e.g. cerebellar pathology. The rhythm also tends to be disordered
Loss of muscle control: high-stepping	May be due to loss of proprioception or a drop foot. This leads to difficulty in clearing the toes during the swing phase and the patient compensates by externally rotating the leg and flexing the hip and knee
Deformity: in-toeing	Can be caused by persistent femoral anteversion. The foot may catch on the back of the calf of the weight-bearing leg, tripping the patient

Figure 33.26 Hip movements: (a) internal rotation; (b) external rotation; (c) adduction; (d) abduction.

Summary box 33.8

Hip examination

Inspection of the standing patient

- Front – pelvic tilt, rotational deformity
- Side – lumbar lordosis
- Back – pelvic tilt, scoliosis, gluteal wasting
- Gait – Trendelenburg, antalgic

Inspection of the supine patient

- Skin, scars, soft tissues, deformity
- Palpation of the anterior joint line, adductor origin, greater trochanter, ischial tuberosity

Movements

- Flexion and extension
- Abduction and adduction
- Internal and external rotation

Special tests

- Thomas's test
- Leg length assessment – real/apparent
- Trendelenburg test
- Snapping hip
- Impingement tests

- **Impingement test.** To assess for femoroacetabular impingement, perform two tests: hip flexion at greater than 90° combined with some adduction and internal rotation (FADIR test). The second test is placing the hip into flexion,

Figure 33.27 Modified Thomas's test for assessing a fixed flexion deformity. A fixed flexion deformity of the right hip is indicated by an inability to fully straighten the right leg (arrow).

full adduction and external rotation. A positive test is indicated by pain.

CLINICAL EXAMINATION OF THE KNEE

The knee is a synovial hinged joint. There are three compartments: medial, lateral and patellofemoral. The quadriceps, quadriceps tendon, patella, patella tendon and tibial tuberosity comprise the extensor mechanism of the knee.

The anterior cruciate ligament (ACL) provides primary restraint to anterior displacement of the tibia. The posterior cruciate ligament (PCL) provides posterior restraint of the tibia. The medial collateral ligament (MCL) resists valgus and external rotation forces whereas the lateral collateral ligament (LCL) resists varus forces.

Figure 33.28 (a, b) Trendelenburg test.

Look

Look at the front, sides and back of both knees and for any walking or mobility aids or external appliances.

- **Skin.** Check for scars.
- **Soft tissues.** Look for wasting of the quadriceps and swelling in front of and behind the knee.
- **Bone.** Look for overall alignment (varus or valgus deformity). Measure the intermalleolar distance if a valgus deformity is present. With varus deformity, measure the distance between

the medial aspect of both knees. From the side of the knee look for fixed flexion or recurvatum (hyperextension).

Gait

Look for antalgic gait (osteoarthritis) and varus thrust (collapse of the knee into more varus as weight is taken on that leg).

Feel

- **Soft tissue.** Feel the tendons for quadriceps and patellar tendon rupture.
- **Fluid displacement or stroke test.** First empty the medial side of the knee by stroking any fluid up from the medial side into the suprapatella pouch. Then place your hand on the superior aspect of the suprapatellar pouch and move it inferiorly, attempting to displace any fluid into the knee joint. Maintain your hand at the level of the superior pole of the patella. Now look to see if the normal gutters on either side of the knee are less noticeable because of fluid distension. Stroke the back of your hand over either gutter in turn. Look at the opposite gutter to see if there is cross-filling.
- **Patellar tap test.** This test is used when a large effusion is present. Place one hand on either side of the patella and, with the other hand, push down on the patella. With an effusion, fluctuance is present as the patella moves towards the joint.
- **Bone.** Feel the tibial tuberosity, inferior pole of the patella, patella facets, origin and insertion of the knee ligaments and joint line (medial and lateral). Remember to palpate for any popliteal swellings. Note the height of the patella.

Move

The knee moves principally in flexion (0–135°) and extension (from 0 to –10°) (Figure 33.29). Assess hyperextension by placing one of your hands on the anterior aspect of the distal femur. Now lift the distal tibia with the other hand. Measure the angle or the height that the heel can be lifted off the couch before the knee starts to move.

Perform a lag test to assess the integrity of the extensor mechanism. The patient is asked to lift the whole leg up off the bed (10°) with the knee straight. They are then asked to bend the knee and then try to straighten it again with the leg still held in the air. If they are unable to restraighten the knee they have a positive lag. This indicates significant weakness of the quadriceps mechanism.

In the presence of an apparent fixed flexion deformity of the knee (seen in osteoarthritis), decide if this is arising from the knee or hip joint. To differentiate, sit the patient up with the knees hanging over the edge of the couch; this obliterates the effect of any hip flexion deformity. Passively try to extend the knee fully. With a flexion deformity of the knee, this is not possible.

Special tests

Collateral ligaments

To assess the ligaments, place the leg under your arm. Flex the knee to 10° (not more) to relax the posterior capsule (the MCL and LCL are taut in full extension and lax in flexion). Stress each ligament in turn by applying a valgus or varus force. With your index fingers simultaneously palpate over the collateral ligaments. Assess for signs of instability (excessive opening of the joint). The quality of the end point should be noted (is it firm or spongy?). Compare both sides (Figure 33.30).

Figure 33.29 (a) Knee flexion and (b) extension.

- **Medial collateral ligament.** A lax MCL or deficient lateral compartment may cause knee instability when applying a valgus stress. It is important to note that the valgus stress test should be applied with the knee in 30° of flexion. Valgus

instability in full extension (0°) should alert you to a possible posterior structure injury (e.g. posterior capsule, posterior cruciate ligament).

- **Lateral collateral ligament.** A lax LCL or deficient medial compartment may cause knee instability when applying a varus stress in 10° of flexion. Instability in full extension (0°) suggests injury to the posterior structures. In a suspected lateral injury, evaluation of the peroneal nerve must be performed.

Anterior cruciate ligament

The most sensitive test for evaluation of the ACL is the Lachmann test.

- **The Lachmann test** (Figure 33.31). Flex the knee to 15–30° and pull the proximal tibia gently forwards. Excessive laxity may indicate rupture of the ACL. Anterior translation of the tibia associated with a soft or no end point is a positive test. The test may be negative in chronic ruptures as the ACL stump can scar to the PCL.
- **Anterior draw test** (Figure 33.32a). Flex both knees to 90° and look for a posterior sag (compare the height of the tibial tuberosities looking from the side). This may indicate an injury to the PCL. Stabilise the feet by sitting on them. Now place your hands around the proximal and posterior aspect of the tibia. With your index fingers, push up the hamstrings to encourage them to relax. Now draw the tibia gently forwards and measure any laxity, comparing it with the other knee. The degree of laxity can be graded: grade I (0–5 mm), grade II (5–10 mm) and grade III (>10 mm).

Posterior cruciate ligament

The PCL is the primary restraint to posterior tibial translation between 30 and 90° of knee flexion. At 90°, the PCL accepts 95

Figure 33.30 Assessing the medial (a, b) and lateral (c, d) collateral ligaments.

per cent of the posterior translational forces. Isolated PCL injuries are graded by the degree of posterior translation of the tibia with the knee in 90° of flexion. Look for a posterior sag with the knees flexed to 90°. The posterior draw test is the most reliable clinical test for a PCL injury.

- **Posterior draw test** (Figure 33.32b). Perform the test with the knee flexed to 90°. Push the anterior aspect of the proximal tibia posteriorly and compare any laxity with the other side. If more than 10 mm of posterior tibial translation is noted at 30 and/or 90° of knee flexion, a combined PCL and posterolateral corner injury may be present. An evaluation of the competency of the posterolateral corner is necessary.

Menisci

The presence of palpable joint line tenderness is the most sensitive clinical examination test for a meniscal tear. Flex the knee

Figure 33.31 Lachmann's test: flex the knee to 15–30° and pull the proximal tibia forwards.

Figure 33.32 (a) Anterior draw test for anterior cruciate ligament stability; (b) posterior draw test for posterior cruciate ligament stability.

to 90° and palpate the joint line using your thumb and index finger. Note any areas of tenderness. The well-known tests for meniscal tears (McMurray's test and Apley's grind test) are unreliable and so are not described here. In the Thessaly test, the patient stands on the bad leg, rotating their body to twist the knee. This test is performed with the knee flexed first to 25° and then 45°. Pain and giving way is diagnostic of a meniscal tear. (You may need to support the patient by holding their hands during this test, if they are not to fall.)

Patellofemoral joint

The patella normally enters the trochlea from a lateral position and becomes centralised with increasing knee flexion, travelling in a 'J' pattern.

- **Patellar tracking** (Figure 33.33). Sit the patient and ask them to let their legs hang off the end of the couch with the knees flexed to 90°. Ask the patient to slowly extend the knee to full extension. Toward the end of extension, look for lateral subluxation of the patella ('J' sign). This indicates maltracking.
- **Patellar apprehension (Fairbank's) test (for instability)**. Attempt to laterally displace the patella with the knee in extension. Patients with instability contract their quadriceps muscle or complain of pain. With the patient supine and the quadriceps relaxed, flex the knee to 30° while trying to push the patella laterally. With instability the patient may react with apprehension. In addition, the quadriceps muscle may contract in an attempt to realign the patella.

Patellar tendon

The patellar tendon serves as the distal extent of the extensor mechanism. Rupture usually occurs at the osseotendinous junction. This results in an inability to actively perform and maintain full knee extension. A rupture presents with diffuse swelling in the anterior knee. A high-riding patella (patella alta) is present secondary to the unopposed pull of the quadriceps muscle. A defect in the tendon is usually palpable. When the rupture extends through the medial and lateral retinaculæ, active extension is lost (Summary box 33.9).

Summary box 33.9

Knee examination

Inspection of the standing patient

- Front – alignment (varus/valgus/rotational deformity), muscle bulk
- Side – fixed flexion deformity
- Back – popliteal swellings, hamstrings
- Gait – antalgic, high stepping gait (foot drop), varus thrust

Inspection of the supine patient

- Skin, scars, soft tissues, deformity
- Palpation of the extensor mechanism, medial and lateral joint lines and collateral ligaments, hamstrings, tibial tuberosity, fibular head

Movements

- Flexion and extension

Special tests

- Patellar apprehension test and extensor mechanism
- Cruciate ligaments
- Collateral ligaments
- Menisci

Figure 33.33 (a, b) Patellar tracking.

CLINICAL EXAMINATION OF THE FOOT AND ANKLE

The foot can be divided into three parts: the hindfoot (calcaneus, talus), the midfoot (navicular, cuboids, cuneiforms) and the forefoot (metatarsals and phalanges).

Look

Ask the patient to stand and assess the overall limb alignment. Assess pelvic obliquity, limb length discrepancy (and its level), valgus/varus deformities of the knee and rotational alignment. Check for contractures of the hips and knees. Now focus your attention on the foot itself:

- **Foot shape.** Assess the overall shape of the forefoot from the front. From the side, look for the normal medial arch (Figure 33.34a). The hindfoot is best appreciated from behind. Now look at the vertical relationship between the Achilles tendon and the calcaneus (normal heel valgus of 5–7°). Look from behind and count the number of toes that can be seen. The ‘too many toes’ sign demonstrates increased forefoot abduction (pes planus (flat foot)) and a splayed forefoot. Foot shapes that may be encountered include neutral foot (no overall deformity), skew foot (hindfoot valgus and forefoot adduction), metatarsus adductus (neutral hindfoot and adduction of the metatarsus), pes planus (collapse of the medial arch) and pes cavus or high arch (increased medial arch). The possible causes of pes planus and pes cavus are shown in Summary boxes 33.10 and 33.11, respectively.

Summary box 33.10

Causes of pes planus

- Normal variant
- Hyperlaxity syndrome, e.g. Marfan’s syndrome
- Tarsal coalition – rigid and painful flat foot (Figure 33.39a)
- Tibial posterior dysfunction

Summary box 33.11

Causes of pes cavus (Figure 33.34b)

- Spinal anomalies, e.g. spina bifida
- Hereditary sensorimotor neuropathies, such as Charcot–Marie–Tooth disease
- Charcot foot (e.g. neuropathic foot)
- Post-compartment syndrome (e.g. Volkmann’s ischaemic contracture)

- **Skin.** A bunion or red swelling on the medial aspect of the metatarsophalangeal joint (MTPJ) is common. This is an area of inflamed skin with an underlying subcutaneous bursa and a joint osteophyte. Systemic manifestations include gouty tophi and thin fat pads under the metatarsal heads as seen in rheumatoid arthritis. Corns are callosities which form where toes rub against the inside of shoes. Remember to assess the appearance of the nails.
- **Soft tissues.** Swelling may indicate soft tissue or joint pathology. Muscle wasting is most commonly seen on the dorsum of the foot and in the clefts between the metatarsals. If present, a full neurological examination of the upper and lower limbs should be performed including the spine.
- **Bones.** Look for any bony prominences or exostoses. Common forefoot deformities are shown in Table 33.12.

Gait

Look for a high stepping gait (foot drop), painful (antalgic) gait (ankle and foot joint pain) and a short propulsive phase (forefoot pain).

Footwear

Inspect the footwear. This may reveal areas of abnormal weight bearing. With normal wear of the sole, a corner is typically worn off the posterolateral aspect of the heel (heel strike). In addition,

Figure 33.34 (a) Normal medial longitudinal arch of the foot. (b) Clinical and radiological appearance of pes cavus.

there may be a circular wear pattern under the ball of the big toe (toe-off phase).

- **External appearance:** Look at the materials used, the metal supports and heel raise, depth and width.
- **Internal appearance:** Look at the insoles, arch supports and heel cups.

Feel

- **Skin.** Reduced sensation in a glove and stocking distribution is seen with diabetes.
- **Soft tissues.** The posterior tibial and the dorsal pedis pulses should be identified (Figure 33.35). Palpate the tibialis anterior tendon and the long extensor tendons on the dorsum of the foot. From the back, palpate the Achilles tendon. Palpate the peroneal tendons from the lateral side and the tibialis posterior tendon from the medial side. The sinus tarsi can be assessed. This is an anatomical space bounded by the talus and calcaneus and is recognisable as a soft-tissue depression anterior to the lateral malleolus. It is filled with fat and the extensor digitorum brevis muscle. Sinus tarsi syndrome may occur. This may be caused by injury to the interosseous talocalcaneal ligament

or the subtalar joint. There is pain and tenderness over the sinus tarsi with subjective hindfoot instability. The pain is characteristically relieved by local anaesthetic injection.

- **Bones.** Feel for deformity, bony prominences and loose bodies:
 - ankle joint: the medial and lateral malleoli, anterior and posterior joint line, lateral gutter and ligament complex, the syndesmosis (front of the ankle), medial gutter and medial ligament complex;
 - subtalar joint: palpate each facet;
 - midtarsal joints: the talonavicular and calcaneocuboid joints;
 - tarsometatarsal joints (TMTJ): note that the second TMTJ is several millimetres proximal to the others; movement is minimal in the second ray, limited in the third ray, moderate in the fourth and fifth rays and very variable in the first ray.
- **Specific structures to palpate:**
 - calcaneus (heel bone): the most common cause of pain is plantar fasciitis; this may present with numbness, burning and electric shock sensations, which are worse in the morning and improve as the day goes on; identify the exact point of tenderness;
 - tendons: examine for contracture of the Achilles tendon insertion and the peroneal or tibialis posterior tendons;
 - head of talus: invert and evert the patient's foot;
 - sustentaculum tali: palpate one fingerbreadth below the medial malleolus; this important structure serves as an attachment for the spring ligament;
 - cuneiforms (medial, middle and lateral), MTPJs, web spaces and all the forefoot bones.

Move

The movements of the foot and ankle are linked via the ankle, subtalar and midfoot joints. Remember the acronyms PAED – pronation, abduction, eversion and dorsiflexion – and SAPI – supination, adduction, plantarflexion and inversion. These are the two common general foot deformities.

Ankle (Figure 33.36)

- **Dorsiflexion.** Test dorsiflexion with the knee both flexed and extended. If restriction is greater with the knee extended than flexed, the contracture is principally in the gastrocnemius. Restriction that is equal in all knee positions is caused by a contracture principally of the soleus.
- **Plantarflexion.** Ask the patient to touch the floor with their foot (15°). Weakness suggests injury to the Achilles tendon or pathology affecting the S1 nerve root.

Subtalar joint (Figures 33.37 and 33.38)

Hold the talar neck and ask the patient to move their heel from side to side. Repeat using a hand on the heel to move the joint and apply a varus and valgus stress while feeling for movements of the talus. Holding the talus as opposed to the tibia isolates subtalar from ankle motion. (Normal range is 5° in each direction.)

Pierre Marie, 1853–1940, Neurologist, Hospice de Bicêtre, Paris, France, later became Professor of Pathological Anatomy in the Faculty of Medicine, and finally, in 1918, Professor of Neurology.

Howard Henry Tooth, 1856–1925, Physician, St Bartholomew's Hospital and the National Hospital for Nervous Diseases, Queen's Square, London, UK, described peroneal muscular atrophy in 1886, independently of Charcot and Marie.

Table 33.12 Common forefoot deformities.

Deformity	Metatarsophalangeal joint	Proximal interphalangeal joint	Distal interphalangeal joint
Claw toe	Hyperextension	Flexion	Flexion
Hammer toe	Normal	Flexion	Flexion
Mallet toe	Normal	Normal	Flexion
Hallux valgus or varus	Valgus or varus position	Normal	–

Figure 33.35 (a) Palpation of the posterior tibial pulse; (b) palpation of the dorsalis pedis pulse.

- **Inversion.** Ask the patient to move their foot in towards them.
- **Eversion.** Ask the patient to move their foot out to the side.

Midtarsal joint

Hold the heel with one hand and move the forefoot medially (adduction = 20°) and laterally (abduction = 10°) with the other hand.

Tarsometatarsal joint

Hold the midfoot and manipulate each metatarsal up and down to estimate the passive range of movement.

Metatarsophalangeal joint

Test extension (70–90°) by asking the patient to lift the toes to the ceiling and test flexion (45°) by pointing the toes to the floor. Normal toe-off requires 35–40° of dorsiflexion.

Special tests

Achilles tendon

Feel the gastrocnemius and soleus bellies and the whole length of the tendon for gaps (rupture), tenderness or swelling. Also identify the posterolateral (Haglund’s) prominence of the calcaneus and palpate the retro-Achilles bursa.

The best test for integrity of the tendon is the **Thompson’s** or **Simmonds’ test**. Do not be misled by the patient’s ability to stand on tiptoes – some people can do this using their long toe flexors alone. Lie the patient prone and allow the calves to rest on your forearms. Squeeze each calf in turn and watch for movement at the ankle joint. Lack of movement may indicate a rupture.

Figure 33.36 (a) Ankle dorsiflexion and (b) ankle plantarflexion.

Subtalar joint flexibility

Ask the patient to stand on their toes and observe the heel from behind; the heel moves normally from valgus to varus indicating flexibility. The **Coleman's block test** is used to assess the flexibility of the subtalar joint. Ask the patient to stand on a 2-cm block with the great toe over the medial edge, resting on the floor. Now look from behind. If the hindfoot varus remains, the subtalar joint is fixed. If it corrects to valgus, the joint is mobile (Figure 33.38).

Flat foot flexibility

Use the Windlass and Jack's test to distinguish a flexible from a fixed flat foot (Figure 33.39):

- **Windlass test.** Ask the patient to stand on their toes and observe the arch of the foot on the medial aspect. As soon as the patient stands on their toes, the arch forms. Failure of this indicates a fixed flat foot.
- **Jack's test.** With the patient standing, lift up the great toe. The arch should form in the flexible flat foot.

Ankle stability

Trauma to the ankle is a common cause of instability. Accurate assessment may be difficult in the acute setting because of pain.

- **Anterior draw test.** With the foot resting over the bed, hold the heel with one hand and the front of the tibia with the other. Move the heel forwards on the fixed tibia. Compare with the other side. Instability of the syndesmosis may be palpable (Figure 33.40).
- **Squeeze test for distal tibiofibular stability.** Compress the proximal calf. Pain at the ankle may indicate separation of the distal fibula from the tibia.
- **Tilt test.** Hold the talus at the neck rather than the heel so that you can be sure that any tilt is in the ankle and not the subtalar joint.

Tarsometatarsal joint stability

Stability can be assessed by pushing each joint up and down. Standing lateral radiographs may be used in addition.

Figure 33.37 Testing subtalar joint motion.

Tibialis anterior

Ask the patient to walk on their heels with their feet inverted; the tibialis anterior tendon can be seen. With the patient's feet resting over the edge of the couch, ask the patient to actively dorsiflex and invert their foot to reach your hand. Palpate the tibialis anterior muscle.

Tibialis posterior

Pathology of the tibialis posterior typically presents with posteromedial ankle pain, swelling and gradual onset of a flat foot. When assessing the tendon, look for swelling along its course, a flat foot with heel valgus, the 'too many toes' sign and prominence of the talar head. Palpate for tenderness, swelling or gaps in the tendon. To test integrity:

- Ask the patient to perform a single foot tiptoe test on both sides. The inability to lift the affected heel off the ground is suggestive of a tibialis posterior tendon injury or insufficiency.
- To test strength, position the foot in the plantarflexed and inverted position. Ask the patient to hold this position while you push against their foot.

Dorsiflexors

Tendinitis of the long toe dorsiflexors usually presents in athletes. Pain affects gait in the early contact phase. Palpate for swelling, gaps or any tenderness. Ask the patient to move the foot into dorsiflexion and to hold this position while you push the foot down.

Figure 33.38 Testing subtalar joint flexibility.

Figure 33.39 (a) Flat foot appearance with a reduced medial longitudinal arch; (b) Windlass test; (c) Jack's test.

Inability to dorsiflex the foot is referred to as foot drop. Causes include stroke, spinal injury, spinal stenosis or disc prolapse, peripheral nerve injury (e.g. sciatic, common and deep peroneal) or a peripheral neuropathy.

Peroneals

Peroneal tendon pathology presents with swelling and/or pain of the lateral hindfoot or midfoot. There may be a history of the ankle 'giving way'. Presentations of peroneal tendon pathology include:

- 'peroneal spasm': may be seen in tarsal coalition; here, the muscles are usually contracted secondary to the hindfoot valgus;
- peroneal tendon dislocation: attempt to dislocate the tendons by dorsiflexing and everting the foot.

The peroneus longus may be palpated just before it crosses under the foot to insert onto the base of the first metatarsal. Ask the patient to plantarflex the first metatarsal. Test strength and integrity by active and resisted eversion while you palpate the tendons for swelling, tenderness or gaps.

Figure 33.40 Anterior draw test.

Morton's neuroma

This condition represents thickening of the tissue that surrounds the digital nerve leading to the toes as the nerve passes under the ligament connecting the metatarsals in the forefoot. It is most frequent between the third and fourth toes. A neuroma presents with burning pain in the ball of the foot that radiates to the involved toes. The condition is difficult to diagnose and requires a high index of suspicion. Palpate in the web space between the symptomatic toes for a mass. Compression of the metatarsals may elicit a 'click' between the bones (Molders' click) (Summary box 33.12).

Summary box 33.12

Ankle and foot examination

Inspection of the standing patient

- Front – alignment, foot shape and deformity
- Side – medial arch
- Back – heel position
- Gait – antalgic, high stepping gait (foot drop)

Inspection of the supine patient

- Skin, scars, soft tissues, bony deformity
- Palpation of the ankle, subtalar, midfoot and forefoot joints

Movements

- Dorsiflexion, plantarflexion, inversion, eversion

Special tests

- Flexibility of the subtalar joint and a flat foot
- Joint stability, Morton's neuroma
- Tendons – tibialis posterior and anterior, Achilles tendon, peroneals and dorsiflexors

CHAPTER 34

Sports medicine and sports injuries

LEARNING OBJECTIVES

To understand:

- The important issues behind a patient's sporting injury in the context of taking a history

To know:

- The common sports injuries

- The appropriate ways of imaging to confirm or refute a diagnosis

To assess:

- The patient and offer treatment and rehabilitation plans

INTRODUCTION

Regular physical exercise is integral to the body staying healthy. However, stressing the human body to its limits may lead to injury. Sports medicine is the science of understanding how these injuries can be avoided, recognised when they do occur, and then treated appropriately. Sports injuries are, in principle, the same as other injuries. The major difference can be in the expectation of the patients. The injuries can be classified into three broad groups. Acute extrinsic injuries are those which arise from a direct external blow. These are commonly wounds, bruises and fractures. Acute intrinsic injuries result from failure of a patient's structures as a result of excessive loading. Examples are tendon ruptures, avulsion fractures and ligament injuries. Chronic injuries are those with an insidious or unknown onset, commonly inflammation or failure secondary to repetitive loading. Examples are inflammation of the Achilles tendon and stress fractures (Summary box 34.1).

Summary box 34.1

Types of sports injury

- Acute extrinsic – caused by direct external blow (bruises)
- Acute intrinsic – internal failure secondary to excessive external force (ligament tear)
- Chronic – repetitive and stress injuries

DIAGNOSIS OF SPORTS INJURIES

There are some additional questions which need to be asked in the history when treating a patient with a sports injury:

- 1 How was the injury sustained?
- 2 What type of sport or training were they undertaking; mixed training or only one type of sport?

- 3 Have they had a previous injury? When was this and what rehabilitation have they had?
- 4 What were they aiming for in the way of competitions or level of sport that they performed before the injury?
- 5 Do they now want to compete again or are they considering retiring?

The examination should follow the system described in Chapter 26.

TENDON DISEASE

Tendons can become weak and/or painful as a result of physical damage or as a result of inflammation of the tendon sheath around them (peritendonitis).

Tendon injury is either due to overload (the strength of the tendon being exceeded by the force applied) or to overuse (where there is repetitive low level load to the tendon) leading to fatigue and failure. In this case the patient may present with inflammation rather than rupture.

Overuse injuries

Internal factors

Overuse injury can be precipitated in a tendon by decreased oxygen supply, decreased nutrition, hormonal changes, chronic inflammation and ageing.

External factors

A change in the environment (new running surface), or worn out equipment (old running shoes), may both bring about an overuse injury as can excessive training when the patient is not fit enough to tolerate it.

In younger patients, the weakest area of a tendon is the apophyseal attachment. In adults, the musculotendinous junction is more liable to injury. In adolescents, the common sites of injury are tendon insertions. Examples are the anterior superior

iliac spine (origin of Sartorius), the anterior inferior iliac spine (rectus femoris), the lesser trochanter of the femur (iliopsoas) and the ischial tuberosity (hamstrings) (Summary box 34.2).

Summary box 34.2

Problems with tendons

- Rupture due to excessive loads
- Pain and inflammation due to repetitive or abnormal loading

MUSCLE INJURY

Muscle injuries can be classified into a sprain, partial tear, complete tear or re-tear (if there has been previous injury). Most will heal spontaneously but may leave a painless defect in the muscle belly.

LIGAMENTS

Ligament injuries are acute intrinsic injuries and can be graded according to their severity (Table 34.1).

Table 34.1 Ligament injuries graded according to severity.

Grade	Description
0	Normal ligament
1	No increase in joint laxity but there is tenderness around the injured ligament
2	Partial disruption of the ligament fibres with increased joint laxity, and a soft end point
3	Complete disruption of the ligament. There is a marked increase in joint laxity with no end point clinically

In the acute phase it may be difficult to assess the ligament injury thoroughly. Once the acute injury has settled then any difference in laxity when comparing the two sides is diagnostic. However, the laxity of ligaments varies dramatically between patients and with age, so absolute measurements are not reliable. Grade 1 and 2 ligament injuries can be treated with pain relief, splinting and gentle mobilisation to avoid stiffness. Grade 3 injuries may require surgical repair to bring together the torn ends of the ligament (Summary box 34.3).

Summary box 34.3

Ligament injuries

- Difficult to assess in the acute phase
- Use the opposite side for comparison
- Surgical repair may be needed for complete disruption

BURSAE

Bursae are found between the joints and overlying tissues or muscles and tendons and are small fluid-filled endothelium-lined

sacks. They decrease frictional forces between structures, but can become inflamed. The most commonly affected sites are over the first metatarsal phalangeal joint (bunion), in front of the patella (housemaid's knee) and behind the elbow (olecranon bursa). They can become inflamed or even infected. If they fail to settle with appropriate treatment then they can be surgically excised.

BONE FRACTURES AND STRESS FRACTURES

True fractures can be encountered in any sport, but the fracture type found more commonly in sportsmen and women is a stress fracture. This is caused by multiple repetitions of moderate loads. Clinically, these lesions give poorly localised pain, which is worse on exercise. They are more common in runners, especially women who may have reduced bone density. The most common sites for stress fractures are the metatarsals and the tibia.

INJURIES ASSOCIATED WITH INDIVIDUAL SPORTS

Golf

The shoulder and back are the most common sites of overuse injuries. Golfer's elbow or medial epicondylitis is due to a common flexor origin tendinosis. It does not just occur in golfers.

Tennis

Tennis elbow is inflammation of the common extensor origin. Partial ruptures of the calf muscles, especially the medial head of the gastrocnemius are also found in tennis players (called tennis leg), and in other sports requiring sudden extreme acceleration.

Rowing

The common problems with rowing are rib fractures and intercostal muscle tears and tendon problems such as intersection syndrome (a tendinosis where the first and second extensor tendon compartments cross) (Figures 34.1 and 34.2).

Football

The main injuries are fractures, groin injuries, muscle tears and twisting injuries to the knees and ankles leading to ligament tears (Figures 34.3 and 34.4). Injuries specific to football include turf toe and neuromas to the deep peroneal nerve due

Figure 34.1 Rowers in action at a regatta (© Vladislav Gagic-Fotolia).

Figure 34.2 Coronal magnetic resonance imaging of the chest showing an intercostal muscle injury in a rower.

to repetitive trauma from kicking the football. Goalkeepers get wrist and hand injuries, including occult scaphoid fractures.

Rugby

This is a high intensity contact sport so injuries include concussion due to head trauma, neck injuries including fractures to the cervical spine, muscle tears, shoulder, acromioclavicular joint and finger injuries including dislocation of the phalanges and tendon injuries e.g. Rugby jersey finger – where there is injury to the flexor profundus tendon.

Javelin throwers

Javelin throwers get injuries due to abnormal stresses on the elbow similar to those seen in baseball. This causes abnormalities of the ulnar collateral ligament and capitellum.

Swimming

Shoulder injuries are more common in swimmers, especially in those performing the crawl or the butterfly stroke as these can lead to impingement syndromes (rotator cuff tendinitis and tears).

Figure 34.3 A footballer in action (© lilufoto-Fotolia).

Figure 34.4 Ultrasound showing a patellar tendinosis with neovascularisation in a footballer.

Volleyball, netball and basketball

Hand injuries are common, as is patellar tendinopathy and internal derangements of the ankle and knee.

Ballet dancing

Ballet dancers get problems with posterior impingement of the ankle and tendinopathy of the flexor hallucis longus tendon when working on pointe (tip-toe) (Figures 34.5 and 34.6). Stress fractures are also found in female ballet dancers due to the abnormal stresses. Male ballet dancers are prone to back and shoulder injuries due to carrying ballerinas.

Young dancers often complain of clicking and pain around the hip which may be due to iliopsoas tendinopathy.

Snowboarders and skiers

Both sports have the full range of injuries associated with a high speed sport (Figure 34.7). The rigid high boots used by skiers protect the ankle, but increase the loads transmitted up the limb, risking fracture of the tibia, and ligament disruption of the knee (especially the anterior cruciate) (Figure 34.8). Novice snowboarders get wrist fractures.

Figure 34.5 Ballet dancer on pointe (© Zoja-Fotolia).

Figure 34.6 Magnetic resonance imaging STIR (short TI inversion recovery) sequence showing a stress injury to a metatarsal (arrow).

Martial arts: judo, karate and taekwondo

All are associated with acute extrinsic injuries (direct blows), and acute intrinsic injuries (failure of ligaments and other structures due to sudden excessive loads).

Weight training

Weight training tends to produce the third type of sports injury (chronic) with problems with the shoulders and carpal tunnel syndrome and the spine.

Kayaking

There are problems with the forearm and posterior interosseous nerve compression.

Marathon runners

Problems include iliotibial band syndrome and stress fractures in the feet and shins.

Figure 34.7 Skiers in action (©Alexander Rochau-Fotolia).

INJURIES ACCORDING TO REGION OF SYMPTOMS

Pelvis, hip and thigh injuries

- **Thigh bruise (Charley Horse, corked thigh or helmet thigh):** These occur in all contact sports and can be both large and painful. They require prolonged rest as they are slow to settle and can rebleed. A pseudo-tumour may develop. Surgical drainage should be avoided if at all possible as it can lead to infection of the haematoma.
- **Quadriceps tears:** These most commonly occur in the rectus femoris muscle. They may be due to a direct blow, but more commonly they are due to twisting injury and they occur along the aponeurosis of the rectus femoris, which is a weak point where the two muscle bellies join.
- **Complete quadriceps rupture** is less common, but may occur when kicking balls or in older patients. The patient can often perform a straight leg raise due to trick manoeuvres. However, they cannot restraighten the raised leg (quadriceps lag). Surgical repair is not usually needed.
- **Hamstring injury** commonly occurs due to twisting injuries following sudden and maximal muscle contraction. The injuries most commonly occur in the biceps femoris tendon, but can occur in the semimembranosus and to a lesser degree semitendinosus.

Groin pain

This is a very difficult area to assess as referred pain to the groin can come from many sources. These include:

- the hip, (labral tears, and osteoarthritis)
- adductor tendon injuries
- stress fractures of the femur, pubis or stress fractures of the femoral neck
- hernias (these may be small and include femoral and obturator hernias)

Figure 34.8 Knee magnetic resonance imaging showing a significant skiing injury with tears of the anterior cruciate ligament, medial collateral ligament and lateral collateral ligament.

- tumours
- sexually transmitted diseases
- gynaecological and urinary problems
- referred pain from the lumbar spine.

Adductor tendon injuries produce localised tenderness over the adductor origin.

A labral tear of the hip will cause clicking and pain.

Knee injury

Acute

Knee injuries are common in contact sports, and as a result of studded boots applying excessive loads to the knee in rapid turning. If the patient cannot continue playing and the knee swells immediately then there is likely to be blood in the knee. The most likely causes are a tear of the anterior cruciate ligament, dislocation of the patella (which usually relocates again immediately), and an intra-articular fracture (there will be marrow fat globules visible in the aspirate).

If the patient continues to play and the knee swells later, then the diagnosis is more likely to be a tear of a meniscus and the fluid aspirated will be clear. The early diagnosis of a knee injury is very difficult as the knee is too painful to examine. Aspiration of any effusion, using full sterile precautions, followed by early physiotherapy to maintain quads strength will allow most acute injuries to settle.

Patellar dislocation is more common in the hyper-mobile patient and in contact sports. If it has not already relocated, straightening the knee allows it to relocate.

Subsequent diagnosis

Patients who have had a patellar dislocation will have a patellar apprehension sign (see Chapter 31).

True locking is caused by a loose body in the knee (osteochondritis dissecans), or a torn meniscus. The patient will be moving normally at the time (unlike pseudo-locking) and will suddenly find that they are unable to straighten or even bend the knee. After a period of 'jiggling' the knee they may be able to release the block and move normally again. The Thessaly test is said to have high sensitivity and specificity for this condition (see Chapter 33) but the MacMurray test does not, so is no longer included. Imaging should be performed in locked knees as clinical assessment is difficult and an arthroscopy may not be needed.

If the meniscal tear is peripheral (where there is a blood supply) then meniscal repair should be undertaken.

Giving way can be caused by weakness, pain or instability. Weakness will usually be the result of quadriceps wasting secondary to the injury and is best treated with physiotherapy.

Patellofemoral pain can arise spontaneously in adolescents, but can also arise after a knee injury when the vastus medialis wastes rapidly, and the patella starts to mal-track. Clinically the patient will give a history of finding it difficult to descend stairs and experience severe pain and giving way when trying to move the knee after a period when it has been held still (pseudo-locking). Once again, physiotherapy is the treatment of choice.

Instability may be the result of disruption of the anterior cruciate ligament with or without medial collateral ligament damage. The knee will give way on twisting or turning, and on examination the pivot shift test will be positive and reproduce the patient's symptoms (see Chapter 33).

If physiotherapy fails to build the patient's muscles enough to stabilise the knee (it often does succeed) then reconstruction of the cruciate ligament must be considered, using a synthetic graft or a length of tendon transferred from elsewhere (Summary box 34.4).

Summary box 34.4

Knee injuries

- Very difficult to examine in the acute stage
- Effusions should be aspirated and early physiotherapy started
- Patella dislocations will have a positive apprehension sign
- Cruciate reconstruction should only be undertaken once the patient has been given a trial of physiotherapy

Iliotibial band syndrome is due to a friction injury of the iliotibial band both proximally over the greater trochanter and distally over the tibia. It occurs most commonly in long distance runners, such as marathon runners, and occurs proximally in females and distally as it extends over the lateral femoral epicondyle in males. If it does not respond to stretching and rest then sometimes steroid injections can help.

Ankle injury

Ankle sprains are the most common cause of morbidity. Most of these injuries occur due to inversion, when the lateral ligament complex and fibula and lateral talus can be injured. Eversion or abduction injuries are much less common and will cause trauma to the medial ligament complex.

The ankle should only be x-rayed if the Ottawa ankle rules are fulfilled as otherwise the likelihood of a fracture is very low. The Ottawa ankle rules are:

- bone tenderness along the distal 6 cm of the posterior margin of the lateral malleolus;
- bone tenderness along the distal 6 cm of the posterior margin or at the tip of the medial malleolus;
- inability to weight bear at the time of the accident or at the time of examination.

Ankle dislocations should be reduced immediately as otherwise necrosis of the tented skin will occur.

Sprains of the ankle should be treated with analgesia, ice and elevation, then a physiotherapy programme started to reintroduce proprioception to the ankle. If this is not done, repeat injuries are more likely.

In adolescents, the peroneal tendon retinaculum can be torn. This leads to a subluxing peroneal tendon, with a painful flicking sensation over the lateral malleolus. In younger patients this is best treated by immobilisation for a month, but if this does not resolve the problem then surgical intervention may be needed (Summary box 34.5).

The Achilles tendon is a common site for tendinosis due to repetitive trauma. There is a fusiform swelling of the central tendon.

Tendon rupture classically occurs in middle-aged squash and badminton players. Simmonds' or Thompson's test is usually diagnostic (see Chapter 33). The tendon can be allowed to heal in plaster with the foot plantar flexed to bring the tendon ends

Summary box 34.5**Ankle injuries**

- Dislocated ankles should be reduced immediately
- X-rays should only be performed if the Ottawa ankle rules are fulfilled
- Physiotherapy to rebuild proprioception reduces the risk of recurrence
- In Achilles tendon rupture Simmonds' test is positive

into contact. This takes several months. Alternatively, a surgical repair can be attempted. This apposes the ends and so should speed return to function, but risks compromising the blood supply to the tendon ends and so delays healing.

Foot injuries

Turf toe is pain, swelling and stiffness in the first metatarsophalangeal joint due to rupture of the plantar plate and injury to the joint capsule following hyperextension of the toe. Treatment is symptomatic.

Stress fractures are a common source of pain in marathon runners. These cause localised pain over a metatarsal on pressure and running. They can be identified by magnetic resonance imaging (MRI) or ultrasound. Navicular stress fractures are difficult to detect clinically and MRI should be performed in unexplained pain. Prolonged rest is the best treatment.

Shoulder and upper limb injuries

Shoulder dislocations occur in contact sports such as rugby. Almost all are anterior. Those who dislocate for the first time should be treated with intensive physiotherapy and rehabilitation. However, over half will have significant anatomical damage (tear of the labrum) (Figure 34.9) and will go on to become recurrent dislocators. In these cases, surgical stabilisation (either open or arthroscopic) is the only treatment.

Figure 34.9 A magnetic resonance arthrogram of the shoulder showing a labral SLAP (superior labrum anterior posterior) tear in a rugby player.

Shoulder instability can also result from overuse. This happens with throwing sports and also sports such as gymnastics, tennis serves and squash.

Tendinosis of the rotator cuff can also occur with overuse in patients who perform overhead sports repetitively, such as tennis players and cricket bowlers. Overload leads to impingement and then inflammation. Subacromial subdeltoid bursitis will cause pain radiating down the arm and to the wrist. This can be worse at night. Impingement can be significant in the overhead position and the patient may have difficulty combing their hair. The supraspinatus tendon can also tear either secondary to impingement or after an acute injury. In the younger athlete this should be repaired surgically.

The acromioclavicular joint can be injured by direct impact in wrestlers, rugby and cyclists. Treatment is usually symptomatic as surgical repair is not easy. If osteoarthritis develops in the joint, the distal end of the clavicle can be excised (Summary box 34.6).

Summary box 34.6**Shoulder injuries**

- Anterior dislocations are initially treated with physiotherapy
- Recurrent dislocations will require surgical stabilisation
- Overuse injuries are common in throwing sports
- Rotator cuff impingement is common
- Torn rotator cuffs should be repaired in young patients

Biceps injuries can occur at the long head of biceps proximally and the distal biceps tendon in weightlifters and wrestlers, but can also occur as part of a significant rotator cuff injury proximally where the rotator cuff can be torn from the supraspinatus across the anterior interval and into the subscapularis tendon. There is no treatment needed.

Arm and hand injuries

Medial and lateral epicondylitis are discussed above (Figure 34.10). There is no reliable treatment apart from symptomatic support.

De Quervain's tenosynovitis occurs in repetitive injuries involving the fingers.

Skiers (or gamekeeper's) thumb occurs where the proximal phalanx of the thumb is forced radially in a fall. The ulnar collateral ligament of the thumb at the level of the metacarpophalangeal joint is damaged. If it is avulsed the aponeurosis of the abductor pollicis brevis can become interposed (a Stener lesion) and so surgical intervention is the only option if this lesion is to repair. Mallet fingers or baseball fingers occur when there is a rupture of the distal insertion of the extensor tendon into the distal phalanx. This can be treated conservatively with a mallet splint.

The radial slips of the extensor tendon can be torn at the level of the metacarpophalangeal joints in boxing injuries and here the retinaculum needs reattaching surgically.

Disruption of the flexor tendon pulleys in the hand occurs in climbers, and leads to bow stringing of the flexor tendons. If this occurs, then surgical intervention is needed (Summary box 34.7).

Figure 34.10 An ultrasound of the common extensor origin at the elbow showing a tendinosis with neovascularisation.

Summary box 34.7

Arm and hand injuries

- Medial and lateral epicondylitis should be treated symptomatically
- Ulna collateral ligament injuries of the thumb require surgical repair
- Flexor tendon pulley injuries require surgical repair

TREATMENT OF INJURIES

In the acute phases of a sports injury PRICE describes the treatment plan:

- Protect
- Rest
- Ice
- Compression
- Elevation.

In the initial phase of an injury, non-steroidal anti-inflammatory drugs are thought to slow healing, but may reduce pain and oedema. This is especially true in fracture healing. Paracetamol and codeine have less of an effect on injury healing and can also help with pain relief.

When prescribing any drugs it is important to be aware of the World Anti-Doping Agency (WADA) guidelines on doping for athletes as some substances can be banned in competition and training. Spot checks are performed on athletes so they need to adhere to this throughout the year. A prohibited list is available on the WADA website (www.wada-ama.org).

If steroids are needed to help with the continued rehabilitation then a TUE or temporary use exemption certificate needs to be given to the athlete so that if they are spot checked for drugs they will not be disqualified.

After an initial period of rest, passive movements should be started, followed by more active movements as healing occurs. Physiotherapy is an essential part of rehabilitation and close liaison between the sports doctor and the coach are needed in getting an athlete back to their sport. Steroid treatment should not be used around the Achilles tendon (advice from NICE (National Institute for Health and Clinical Excellence) and the British National Formulary).

Some patients develop myositis ossificans after a muscle haematoma. This presents itself as increasing swelling and pain. It can also be treated by Indomethacin which helps prevent further formation. It resolves naturally.

CHAPTER 35

The spine

LEARNING OBJECTIVES

To learn:

- The salient features relating to the history and examination of the spine
- The investigations commonly used in the field of spinal disorders
- The treatment principles for common conditions affecting the spine

EPIDEMIOLOGY

The lifetime prevalence of low back pain has been reported at between 60 and 80 per cent. By contrast, the lifetime prevalence of true sciatica is between 2 and 4 per cent. It is generally accepted that 90 per cent of acute low back pain episodes settle, allowing return to work within 6 weeks. However, some 5–7 per cent of the population aged between 45 and 64 years will report back problems as a 'chronic sickness'. Up to 70 per cent of acute episodes of sciatica resolve within three months (Summary box 35.1).

Summary box 35.1

Epidemiology

- Low back pain is extremely common
- Ninety per cent of acute low back pain episodes settle within 6 weeks
- Sciatica is much less frequent
- Seventy per cent of acute sciatic episodes settle within three months

CLINICAL ANATOMY

The normal cervical lordosis measures between 35 and 45°. The normal lumbar lordosis is between 40 and 80° (mean 60°) and decreases with age. Most lumbar lordosis occurs between L4 and S1. The normal thoracic kyphosis is between 20 and 50° (mean 35°) and increases with age. When standing, the normal sagittal vertical axis (sagittal plumb-line) falls from the odontoid process through the C7–T1 disc space and crosses the spinal column at the T12–L1 disc space, before reaching the posterosuperior corner of the S1 vertebral body. For an energy efficient posture, cervical and lumbar lordosis will balance thoracic kyphosis.

The spinal canal is formed behind the articulated vertebral body by the posterior elements of the vertebral column and can be divided into a central portion and two lateral portions. The central portion is occupied by the thecal sac containing the spinal cord which terminates behind the body of L1. The lateral portions contain the nerve roots.

The spinal nerve roots comprise eight cervical, twelve thoracic, five lumbar, five sacral and one coccygeal. Dorsal and ventral roots join to form spinal nerves. The ventral root and the dorsal root ganglion lie within the intervertebral foramen. This foramen is bounded superiorly and inferiorly by pedicles, anteriorly by the disc and posteriorly by the facet joint. Degenerative changes in these structures may lead to neural compromise. Laminar overlap within the lumbar spine decreases from L1 to S1 so that, at the L5–S1 level, access to the intervertebral disc requires less bone removal than a more proximal level.

The blood supply of the spinal cord is derived from the vertebral, deep cervical, intercostal and lumbar arteries. The arteries of the spinal cord include the anterior spinal artery and two posterior spinal arteries, with the anterior spinal artery supplying the majority of the vascular supply to the spinal cord. The radicular artery of Adamkiewicz makes a major contribution to the anterior spinal artery, supplying the lower spinal cord. It originates on the left in 80 per cent of people, usually accompanying the ventral root of T9, T10 or T11, but can originate anywhere from T5 to L5. Ligation of this important artery may lead to critical ischaemia of the spinal cord. Ligating segmental vessels over the midpoint of the vertebral body will minimise the risk of injury to this important artery during anterior approaches to the spine.

PATIENT HISTORY

The most common reasons for referral to a spinal clinic include pain and spinal deformity. A detailed history of the pain including site, type, severity, duration, frequency and aggravating

factors should be sought. Has there been any history of trauma? Is the pain present at night? Is there associated pain in the upper limbs (brachalgia) or lower limbs (sciatica)? Is there associated numbness, tingling, weakness, or difficulty with gait? Is there a family history of ankylosing spondylitis or rheumatoid arthritis? Are there concurrent medical conditions such as diabetes, peripheral vascular diseases, osteoarthritis of the hip or previous malignancies? Are there systemic symptoms such as unexplained weight loss, chills or fever? Table 35.1 lists the commonly accepted ‘red flags’ that allow diagnostic triage into those with serious pathology of the spine (such as fractures, tumours, infection or cauda equina syndrome) and those without serious pathology.

Table 35.1 ‘Red flags’: when present in patients with back pain, red flags suggest the likelihood of serious underlying pathology.

Age <20 years or >50 years
Recent significant trauma
History of malignant disease
Unexplained weight loss
Constitutional symptoms (fever, chills)
Immunosuppression (intravenous drug abuse, prolonged corticosteroid use)
Severe or progressive sensory alteration or motor weakness
Acute difficulty with micturition (painless retention)
Numbness in perineum or buttocks and/or faecal incontinence

Pain may be arising from the spine, but non-spinal causes of pain must also be considered (Table 35.2). Patients should always be asked about the presence of perineal numbness (saddle area) and/or difficulties passing urine or faeces, as these symptoms may indicate a cauda equina syndrome (Table 35.3).

Table 35.2 Non-spinal causes of low back pain; referred pain.

Respiratory, e.g. mesothelioma
Vascular, e.g. abdominal aortic aneurysm
Renal, e.g. pyelonephritis
Gastrointestinal, e.g. peptic ulcer, pancreatitis
Urogenital, e.g. testicular, ovarian or prostatic carcinoma

Patients should be asked whether the pain is interfering with their ability to work. What treatment has the patient already tried and how effective were these treatments, e.g. analgesics, exercise, physiotherapy or spinal injections? Pending litigation or workers’ compensation claims may have a negative prognostic effect on future treatments and therefore should be enquired about.

Spinal deformities, e.g. scoliosis and kyphosis are generally painless in children, but may become symptomatic in adult life. How quickly has the spinal deformity progressed? It is important to assess skeletal maturity and whether the child has gone

Table 35.3 Cauda equina syndrome.

Low back pain
Uni- or bilateral sciatica
Saddle anaesthesia
Motor weakness in the lower extremities
Variable rectal and urinary symptoms

through a recent growth spurt? Has menstruation commenced in the female or has the voice dropped in the male?

PHYSICAL EXAMINATION

The patient should be undressed and posture should be evaluated in both the frontal and sagittal plane. Shoulder or waist asymmetry suggests the presence of scoliosis. The Adams’ forward bend test will accentuate trunk asymmetry and allow appreciation of rib or loin prominence on the convex side of the curve. The skin should be examined for cutaneous neurofibromata, café-au-lait patches or axillary freckles commonly present in neurofibromatosis. Neurological examination should include abdominal reflexes. Leg lengths should be measured. In the case of kyphosis, the sagittal alignment and forward gaze should be assessed.

William Adams described the forward bending test for scoliosis in 1865. His understanding of the nature of the rotational element of scoliosis was given by a post-mortem he performed on an eminent surgeon and geologist, Gideon Mantell. The clinical history of Dr Mantell is well documented.

Palpation is useful to locate specific areas of tenderness. Ranges of motion should be assessed. The normal range of motion in the cervical spine is 45° of flexion, 55° of extension, 70° of rotation and 40° lateral bend. The normal range of motion in the lumbar spine is 40–60° of flexion, 20–35° of extension, 15–20° lateral bending and 3–18° of rotation. Schober’s test is a simple clinical test to evaluate spinal mobility. A tape measure is used to mark the skin midway between the posterior superior iliac crests and at points 10 cm proximal and 5 cm distal to this mark while the patient is standing. The patient is then asked to bend forward as far as possible and the distance between the two points is measured with the patient in the flexed position. Normally one would expect to see an increase of at least 5 cm between the two points in the erect and flexed positions.

Neurological examination of the upper and lower limbs will focus on tone, power, coordination, reflexes, sensation and gait (Tables 35.4 and 35.5). A rectal examination should be performed if there is any concern about cauda equina integrity. The superficial abdominal reflex is an upper motor neurone reflex. It is performed by stroking one of four abdominal quadrants in succession. The umbilicus should move towards the quadrant that was stroked. The reflex should be symmetric from side to side. Asymmetry suggests intraspinal pathology (Summary box 35.2).

Myelopathy or upper motor neurone (UMN) lesions are suggested by spasticity, motor weakness, hyper-reflexia, a positive Hoffmann’s sign (if the middle finger is flicked into extension,

Table 35.4 Neurological evaluation of the upper limb.

Neurological level	Motor	Sensation	Reflex
C5	Deltoid	Lateral arm	Biceps
C6	Wrist extensors and extensor carpi radialis longus	Lateral forearm	Brachioradialis
C7	Triceps	Middle finger	Triceps
C8	Long finger flexors	Medial forearm	No reflex
T1	Interosseus muscles	Medial arm	No reflex

Table 35.5 Neurological evaluation of the lower limb.

Neurological level	Motor	Sensation	Reflex
L2	Hip flexion	Anterior thigh, groin	No reflex
L3	Knee extension	Anterior and lateral thigh	Patellar (L3, 4)
L4	Ankle dorsiflexion	Medial leg and foot	Patellar (L3, 4)
L5	Extensor hallucis longus	Lateral leg and foot	No reflex
S1	Ankle plantarflexion	Lateral foot and little toe	Achilles

the thumb and other fingers flex briskly), up-going Babinski response, patellar and ankle clonus. Typical signs of radiculopathy (lower motor neurone (LMN) lesion) include sensory loss, motor weakness, flaccid paralysis, muscle atrophy, loss of reflexes and muscle fasciculation.

The straight leg raise test is performed with the patient in the supine position. The leg is elevated with the knee straight to increase tension along the L5 and S1 nerve roots. The test is positive if the leg elevation provokes radicular pain. Lasègue's sign denotes radicular pain aggravated by ankle dorsiflexion. The femoral stretch test is performed with the patient in the prone position by extending the hip and flexing the knee. This creates tension on the L2, L3 and L4 nerve roots. The femoral nerve stretch test is considered positive if radicular pain occurs in the anterior thigh region during the test.

The examination should include, where appropriate, examination of the shoulder, hip, knee, sacroiliac joint and vascular system, as dual pathology is common in the ageing community.

Waddell developed and validated a series of signs and tests that have proved helpful in identifying individuals who are magnifying or exaggerating symptoms, possibly for secondary gain (Table 35.6) (Summary box 35.3).

INVESTIGATIONS

The most common diagnostic imaging tests used to evaluate spinal disorders include plain radiographs, magnetic resonance imaging (MRI), computed tomography (CT), CT myelography and isotope bone scanning. These investigations are extremely sensitive, but relatively non-specific. For example, at least one-third of asymptomatic patients have been noted to have 'abnormalities' on MRI scans. All investigations must therefore be carefully correlated with the clinical findings.

Table 35.6 Non-organic physical signs in low back pain.

Tenderness	Superficial or non-anatomical
Simulation tests	Axial loading or rotation
Distraction tests	Variable straight leg raises
Regional disturbances	Non-anatomical sensory or motor loss
Over-reaction	Grimacing, muscle tremor, etc.

Summary box 35.2

Upper motor neurone lesion characterised by:

- Increased tone – spastic
- Hyper-reflexia
- Muscle spasms
- Motor weakness
- Disuse atrophy
- Positive Hoffman's sign
- Ankle and patellar clonus
- Upgoing plantar response

Summary box 35.3

Lower motor neurone lesion characterised by:

- Decreased tone – flaccid
- Hyporeflexia
- Denervation fasciculations
- Motor weakness
- Sensory loss
- Severe atrophy
- Downgoing plantar response

Plain radiographs

It is not appropriate to order spine radiographs for every patient presenting with neck or low back pain. Patients with red flag signs or symptoms and those who have not responded to conservative treatment require imaging, but most units in developed countries would use MRI initially rather than x-rays. Standing radiographs of the whole spine are important for the full assessment of scoliosis. Radiographs cannot diagnose early-stage tumour or infection, because significant bone destruction (between 40 and 60 per cent of bone mass) must occur before a radiographic abnormality is detected.

Magnetic resonance imaging

This allows detailed visualisation of the thecal sac, spinal cord, epidural space, intervertebral disc, nerve roots, paraspinal soft tissues and bone marrow. It is contraindicated for patients with pacemakers, some drug pumps or spinal cord stimulators.

Computed tomography

This investigation is the best test for bone anatomy. Three-dimensional reconstructions are often useful for the assessment of congenital spinal deformity.

Bone scintigraphy

Isotope bone scanning is a highly sensitive, but non-specific test useful for screening of the skeletal system for metastatic disease, discitis or vertebral body osteomyelitis, or to assess the relative activity of bone lesions such as pars interarticularis defects or a pseudarthrosis. In the case of multiple myeloma or purely lytic metastases, the bone scan may not show increased activity as these tumours may not stimulate a significant osteoblastic response.

Bone densitometry

Bone density and osteoporosis can be measured using dual-energy x-ray absorptiometry (DEXA).

Provocative discography

This involves the injection of a radio-opaque contrast agent into a presumed degenerated and painful disc in the conscious patient as a preoperative test to elucidate the source of pain before considering spinal fusion or disc replacement (Figure 35.1).

Facet joint injections

For patients with facet joint arthropathy, x-ray-guided local anaesthetic and steroid injections may be both diagnostic and therapeutic.

Foraminal epidural steroid injections

For patients with radiculopathy due to a prolapsed intervertebral disc or lateral recess stenosis, a targeted foraminal epidural steroid injection of local anaesthetic and steroid may provide important diagnostic information and have a lasting therapeutic effect.

Spinal biopsy

CT-guided or open biopsy is often performed to obtain tissue for diagnostic study in cases of suspected tumour and/or infection.

DEGENERATIVE CONDITIONS OF THE SPINE

Cervical radiculopathy

Patients present with neck and arm pain (brachialgia), paraesthesia and motor weakness in the distribution of the compromised nerve root (radiculopathy). This may be caused by disc herniation or degenerative stenosis.

Symptoms often respond to conservative treatment including physiotherapy and medication for neuropathic pain (amitriptyline, gabapentin or pregabalin) or fluoroscopically guided foraminal epidural steroid injections of local anaesthetic and steroid. Intractable pain or functional neurological deficit is an indication for surgical intervention. Surgical options include anterior cervical discectomy (with or without the application of a cervical spine locking plate), posterior laminoforaminotomy or cervical total disc replacement.

Cervical myelopathy

Degenerative change in the cervical spine leading to spinal cord compression is the most common cause of cervical myelopathy in patients over 55 years of age (Figure 35.2). Lower motor neurone changes occur at the level of the lesion, with atrophy of the upper extremity muscles, particularly the intrinsic muscles of the hands. Upper motor neurone findings are noted below the level of the lesion and may involve both upper and lower extremities. If surgery is considered appropriate then an anterior or posterior decompression will be needed.

Thoracic disc herniation

Thoracic disc herniations that require surgical intervention are rare, accounting for less than 2 per cent of all discectomy procedures. Typically, the patient presents with axial pain, radiculopathy or myelopathy. Conservative treatment including non-steroidal anti-inflammatory drugs, physiotherapy and general fitness improvement should be tried initially. If required, thoracic discectomy may be performed via a thoracotomy or, for a soft disc prolapse, via a thoracoscopic approach.

Figure 35.1 Three level discography.

Figure 35.2 Cervical myelopathy. Magnetic resonance image showing a block fusion at C6/7 with adjacent level degenerative changes and compromise of the spinal cord at C3/4, C4/5 and C5/6. Signal change was noted within the cord, particularly at the C4/5 level.

Cauda equina syndrome

Cauda equina syndrome (CES) is rare, accounting for only 2–6 per cent of all lumbar disc herniations. It presents most commonly in the 20–45 year age group with some or all of the following symptoms: low back pain, unilateral or bilateral sciatica, lower limb motor weakness, sensory abnormalities including saddle anaesthesia, bladder dysfunction (painless retention in early stages, overflow incontinence in later stages), sexual and bowel dysfunction. CES may result from acute or chronic compression of the cauda equina nerve roots. The most frequent cause is a massive central lumbar disc protrusion at L4/5; other causes include lumbar fractures, postoperative epidural haematoma, spinal stenosis, spinal tumours, and occlusion of the lumbar arteries by dissection or aneurysm of the abdominal aorta.

Nerve roots within the cauda equina nerve roots lack epineurium and perineurium, and only have a thin endoneurium root sheath making them more susceptible to compression forces when compared to peripheral nerves. The syndrome can result in permanent motor deficit, bladder, bowel and sexual dysfunction. It represents a true spinal emergency and requires urgent surgical decompression. The outcome for patients who undergo surgical decompression within 24 hours of the onset of loss of bladder or bowel control is significantly better compared to those that undergo surgery beyond this 24-hour period (Summary box 35.4).

Lumbar disc herniation

Symptomatic lumbar disc herniation occurs during the lifetime of approximately 2–4 per cent of the population. Risk factors include family history, male gender, age (30–50 years), heavy lifting or twisting, stressful occupation, lower income and cigarette smoking.

Summary box 35.4

Cauda equina syndrome

- Most common presenting symptoms: perineal numbness, painless urinary retention and faecal incontinence
- Urgent investigation with magnetic resonance imaging is required for all suspected cases
- Confirmed cauda equina syndrome requires surgical decompression within 24 hours to achieve optimum outcomes

Over 90 per cent of lumbar disc herniations occur at the L4–5 or L5–S1 levels (Figure 35.3). A posterolateral disc protrusion will affect the traversing root, e.g. an L4–L5 disc protrusion affects the L5 nerve root. A far-lateral disc protrusion (extraforaminal) will affect the exiting nerve root, e.g. a far-lateral L5–S1

Figure 35.3 Far-lateral disc prolapse at L5/S1. A right-sided far-lateral disc protrusion is noted at L5/S1 on the T1-weighted (a) and the T2-weighted (b) magnetic resonance imaging scan. The patient presented with an L5 radiculopathy.

disc protrusion affects the L5 nerve root. Symptoms typically commence with a period of back pain followed by sciatica. There may be paraesthesia, motor weakness, loss of reflexes and a reduction in straight leg raise.

For simple sciatica, a period of 6–12 weeks of conservative treatment is advised. Up to 70 per cent of patients will settle within this period. Transforaminal epidural steroid injections may be helpful. Microdiscectomy is the standard surgical intervention for those in whom conservative treatment has failed. The procedure is carried out in the prone position with radiographic confirmation of the correct level. Loupes with a headlight or use of the operating microscope greatly facilitate the procedure. A 3–5 cm incision is made with a unilateral take down of the multifidus. The spinal canal is entered via removal of the ligamentum flavum under the lamina. The thecal sac and traversing nerve root are identified. The dura and nerve root are retracted medially and the offending disc prolapse incised via a transverse annulotomy. The disc fragment is removed and the disc space cleared of any remaining nuclear material with rongeurs and multiple washouts of the disc space. The wound is closed. Patients are generally discharged the next morning.

Spinal stenosis

Spinal stenosis may be defined as any type of narrowing of the spinal canal, nerve root canal or intervertebral foramen. The resultant nerve root compression leads to nerve root ischaemia presenting with back, buttock or leg pain provoked by exercise. Spinal stenosis may be congenital as is the case in achondroplasia or acquired as is the case for degenerative types (commonly presenting between 50 and 70 years of age). The narrowing is caused by facet joint hypertrophy, disc bulge and ligamentum flavum thickening.

Symptoms of spinal claudication can be distinguished from vascular claudication because they are frequently associated with neurological symptoms, are often worse in extension, and pedal pulses are present on clinical examination. Symptoms progress in approximately 20–33 per cent of patients who receive no treatment. The condition may be treated successfully by surgical decompression with preservation of the facet joints (Summary box 35.5).

Summary box 35.5

Spinal stenosis

- Extremely common condition in the 50–70 year age group
- Classic symptoms: back, buttock, thigh and calf pain
- Provoked by walking and extended posture
- Relieved by flexed posture
- Symptoms progress in up to one-third of untreated patients

Discogenic low back pain

Discogenic low back pain has been defined as a continuum of diagnostic categories (internal disc disruption, degenerative disc disease, segmental instability) reflecting various stages of degenerative pathology affecting the intervertebral disc. Not all degenerate discs are painful. Patients typically present with chronic relapsing episodes of low back pain between the ages of 40 and 60 years old.

A recent study has compared rehabilitation with spinal fusion for discogenic pain. Both groups reported reductions in

disability with the authors strongly recommending a course of rehabilitation before surgical intervention. For those who fail to improve with conservative measures, provocative lumbar discography (Figure 35.1) may help to identify the source of pain, and surgery in the form of lumbar fusion (Figure 35.4) or lumbar disc replacement (Figure 35.5) may be considered. Spondylolysis and spondylolisthesis

Spondylolysis

This is a unilateral or bilateral defect in the region of the pars interarticularis without vertebral slippage. The incidence is reported at approximately 6 per cent by the age of 14 years, but much higher in the young athletic population. Many cases remain asymptomatic. The diagnosis is difficult with x-rays. SPECT (single photon emission computed tomography), reverse gantry CT and MRI scans are helpful. Treatment involves rest, non-steroidal anti-inflammatory medication, activity modification and a lumbosacral orthosis. For patients who remain symptomatic despite an adequate trial of non-operative care, surgery in the form of a direct repair of the pseudarthrosis by a Buck's fusion may be indicated (Summary box 35.6).

Summary box 35.6

Spondylolysis

- Incidence general population 6 per cent by 14 years
- Incidence athletic population 15–47 per cent
- May be complete asymptomatic/incidental finding on x-ray
- Difficult to image, but magnetic resonance imaging proving more useful
- Conservative treatment: activity modification, anti-lordotic brace
- Surgical treatment: direct repair preserving motion or spinal fusion if associated disc degeneration

Spondylolisthesis

Spondylolisthesis is a forward slippage of the vertebral body engendered by a break in the continuity or elongation of the pars interarticularis and present in 4 per cent of the adult population (Figure 35.6). Spondylolisthesis can be classified into six types by causation (Table 35.7), or by the degree of slip (Table 35.8).

For progressive slips in skeletally immature patients (less than 18 years old), those patients with intractable low back or radicular pain, or neurological symptoms, surgery may be indicated. For low-grade slips (Meyerding I and II) fusion *in situ* is the procedure of choice. If there is objective evidence of neural compression (e.g. weakness of extensor hallucis longus), a spinal decompression should be performed at the same time. For high-grade slips (Meyerding III and IV), opinion is divided on whether to reduce the slip first and then fuse, or simply to fuse *in situ*.

TUMOURS OF THE SPINE

Metastatic tumours

These are the most common tumours affecting the spine, accounting for 98 per cent of all spine lesions. The most common malignancies that metastasise to the spine are shown

Figure 35.4 Anterior lumbar interbody fusion. The PEEK (poly-ethyl-ethyl-ketone) cage has been packed with bone graft prior to insertion (a); (b) and (c) show the anteroposterior and lateral postoperative radiographs, respectively.

Figure 35.5 Lumbar total disc replacement. (a) Anteroposterior radiograph with 30° of cranial inclination. (b) Lateral radiograph with the implant appropriately positioned.

in Table 35.9. Red flags picked up on history or examination will alert the clinician to this possible diagnosis.

Over 80 per cent of patients with spinal metastases present with progressive pain, and only 20 per cent present with spinal cord compression. Useful investigations include full blood count (FBC), urea and electrolytes, liver function tests, calcium erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), prostate-specific antigen (PSA), serum protein electrophoresis, thyroid function tests (where a thyroid mass has been palpated) and nutritional indices. Plain radiographs may show an absent pedicle ('winking owl' sign), vertebral cortical erosion and/or vertebral collapse. Whole spine MRI will detect most metastases. Most metastases are osteoblastic and will show up on bone scintigraphy; however, osteolytic lesions such as multiple myeloma and hypernephroma may not show up on an isotope bone scan. Metastases from the prostate may be sclerotic. Biopsies may be obtained via a percutaneous CT-guided method or open biopsy.

Treatment options include orthotics, steroids (dexamethasone), radiotherapy, chemotherapy, hormonal therapy, surgery or a combination of any of the above. Radiotherapy promotes reossification of the vertebral body and reduces tumour load. It can be very effective for reducing 'bone pain'.

Table 35.7 The Wiltse classification of spondylolisthesis.

Type 1	Dysplastic	Associated with congenital deficiency of the L5–S1 articulation
Type 2	Isthmic	Associated with a lesion of the pars interarticularis. Three subtypes: 2A: lytic defect of the pars 2B: elongated or attenuated pars 2C: acute pars fracture
Type 3	Degenerative spondylolisthesis	Segmental instability due to disc degeneration and facet arthrosis
Type 4	Traumatic	Acute fracture in the region of the posterior elements, other than the pars interarticularis
Type 5	Pathological	Generalised bone disease resulting in attenuation of the pars (e.g. metabolic, neoplastic)
Type 6	Post-surgical	After decompression of the lumbar spine

**Figure 35.6** Lytic spondylolisthesis L4/L5. (a) Lateral radiograph showing a Meyerding grade I spondylolisthesis. The patient underwent a decompression and instrumented fusion *in situ* (b).

Lymphoma, breast, lung and prostate metastases are highly radiosensitive. Gastrointestinal adenocarcinoma, metastatic melanoma, thyroid and renal carcinoma are radioresistant. Small

Table 35.8 The Meyerding classification for the degree of slip of spondylolisthesis.

Grade	Per cent
I	1–25
II	26–50
III	51–75
IV	76–100

Table 35.9 Commonest malignancies that metastasise to the spine and their frequency.

Malignancy	Frequency (per cent)
Breast	21
Lung	14
Prostate	7.5
Renal	5
Gastrointestinal	5
Thyroid	2.5

cell carcinoma of the lung, Ewing's sarcoma, thyroid carcinoma, breast carcinoma and neuroblastoma are usually sensitive to chemotherapy and should have chemotherapeutic agents as the first-line management. Adenocarcinoma of the lung is resistant to chemotherapy. Prostate metastases may respond well to anti-androgenic hormone medication.

Extensive reconstructive tumour surgery should be reserved for those patients whose life expectancy exceeds three months. For patients with malignant spinal cord compression, the combination of decompressive surgery with stabilisation and postoperative radiotherapy has been shown to be superior in outcome when compared to radiotherapy alone. In one randomised trial, surgery and radiotherapy permitted most patients to remain ambulatory for the remainder of their lives, whereas patients treated with radiotherapy alone spent a large proportion of their remaining time as paraplegics (Summary box 35.7).

Summary box 35.7**Metastatic tumours of the spine**

- Most common presentation is progressive spinal pain
- Magnetic resonance imaging of whole spine will detect most metastases
- Surgery is indicated for instability pain, progressive deformity or neurological deficit

Primary spine tumours

These may be benign, intermediate or malignant. These are discussed further in Chapter 39.

Benign tumours tend to occur in the posterior elements (Figure 35.7); malignant tumours (Figure 35.8) tend to involve the vertebral body.

Intradural tumours

These are rare. They may be intramedullary (within the substance of the cord) or extramedullary (outside the cord). Most are extramedullary and benign; the most common are meningiomas and neurofibromas. They are discussed in Chapter 39.

INFECTIONS OF THE SPINE**Pyogenic infections**

Pyogenic vertebral osteomyelitis is primarily a lesion of the disc and its osseous margins (Figure 35.9). The most common method by which an organism spreads to the spine is via the haematogenous route. The disc is nearly always involved in pyogenic vertebral infection. In contrast, granulomatous infection, such as tuberculosis, typically does not involve the disc space.

Risk factors for pyogenic vertebral osteomyelitis include advancing age, intravenous drug abuse, diabetes, renal failure, recent infections and trauma. *Staphylococcus aureus* accounts for 30–55 per cent of the infections. Gram-negative organisms such as *Escherichia coli*, *Pseudomonas* species and *Proteus* species are associated with recent genitourinary infections and intravenous drug abuse. Anaerobic infections are uncommon, but may be seen in diabetic patients and after penetrating trauma.

The principles of treatment of bone infection are discussed in Chapter 40.

Operative intervention should be considered for:

- an open biopsy (when a closed biopsy has failed);
- failure of medical management (persistent pain, elevated ESR);
- drainage of abscesses;
- decompression of spinal cord compression;
- correction of progressive spinal deformity;
- stabilisation of progressive spinal instability.

Epidural abscess

This condition is often a surgical emergency. The majority of cases occur within the thoracic spine. Without treatment, neurological deficit including paralysis may develop.

Tuberculosis

Spinal tuberculosis is still unfortunately common in developing countries. Any patient, usually from a lower socio-economic

background, complaining of backache associated with constitutional symptoms such as weight loss, evening pyrexia, cough and malaise should alert one to the possibility of spinal tuberculosis (Pott's disease).

On examination there will be tenderness of the spine over the affected segment. In advanced cases the patient may have a soft fluctuant mass in the right iliac fossa and femoral triangle, the mass exhibiting cross-fluctuation. This would be classical of a cold abscess tracking along the psoas sheath; the patient may be oblivious to its presence. The pathology would be in the lumbar or lower thoracic vertebrae. When the thoracic vertebrae are affected there may be collapse in advanced cases giving rise to a kyphosis (gibbus).

Investigations would show a rise in inflammatory markers (ESR and CRP) and anaemia; sputum is sent for culture and sensitivity as concurrent pulmonary TB is not uncommon. Chest x-ray may show pulmonary TB; spinal x-ray would show vertebral collapse with a para-spinal soft tissue shadow (cold abscess) with absence of psoas shadow. Aspiration of a cold abscess with staining for acid-fast bacilli and culture and sensitivity (this may take a few weeks) is essential. It is important to exclude TB in other sites such as the gastrointestinal and genitourinary systems. MRI and CT scans are also helpful.

Once diagnosed, the patient should be closely managed by a chest physician and spinal surgeon. Full anti-tuberculous chemotherapy and spinal immobilisation is the mainstay of treatment. For further details of treatment, the reader is advised to look up more specialised sources.

INFLAMMATORY SPONDYLOARTHROPATHY**Rheumatoid arthritis**

Between 33 and 50 per cent of patients develop atlanto-axial subluxation (AAS) within five years of diagnosis of rheumatoid arthritis. Some 2–10 per cent of patients with AAS develop myelopathy over the next ten years. Once diagnosed with myelopathy, 50 per cent of patients die within one year. Approximately 20 per cent of patients develop symptomatic subaxial disease. Neurological symptoms may occur as a result of direct compression by bone or soft tissue or from neural ischaemia. Care needs to be taken with these patients whenever they require surgery. The degree of subluxation may need to be checked by performing flexion and extension x-rays, and the theatre staff (especially the anaesthetist) need to be warned to take special care especially with intubation. The indications for surgery to stabilise the cervical spine are given in Table 35.10.

Ankylosing spondylitis

Should a patient with ankylosing spondylitis (AS) present following trauma, a high index of suspicion for occult fractures should be present. It is common for AS patients to develop epidural haematomas with subtle neurological deficit.

Patients with a significant fixed flexion deformity at the cervicothoracic junction ('chin-on-chest' deformity), limited forward gaze, eating and swallowing difficulties may be treated with a closing wedge osteotomy at the cervicothoracic junction (Figure 35.10). Extension osteotomies can also be performed in the thoracic and lumbar spine.

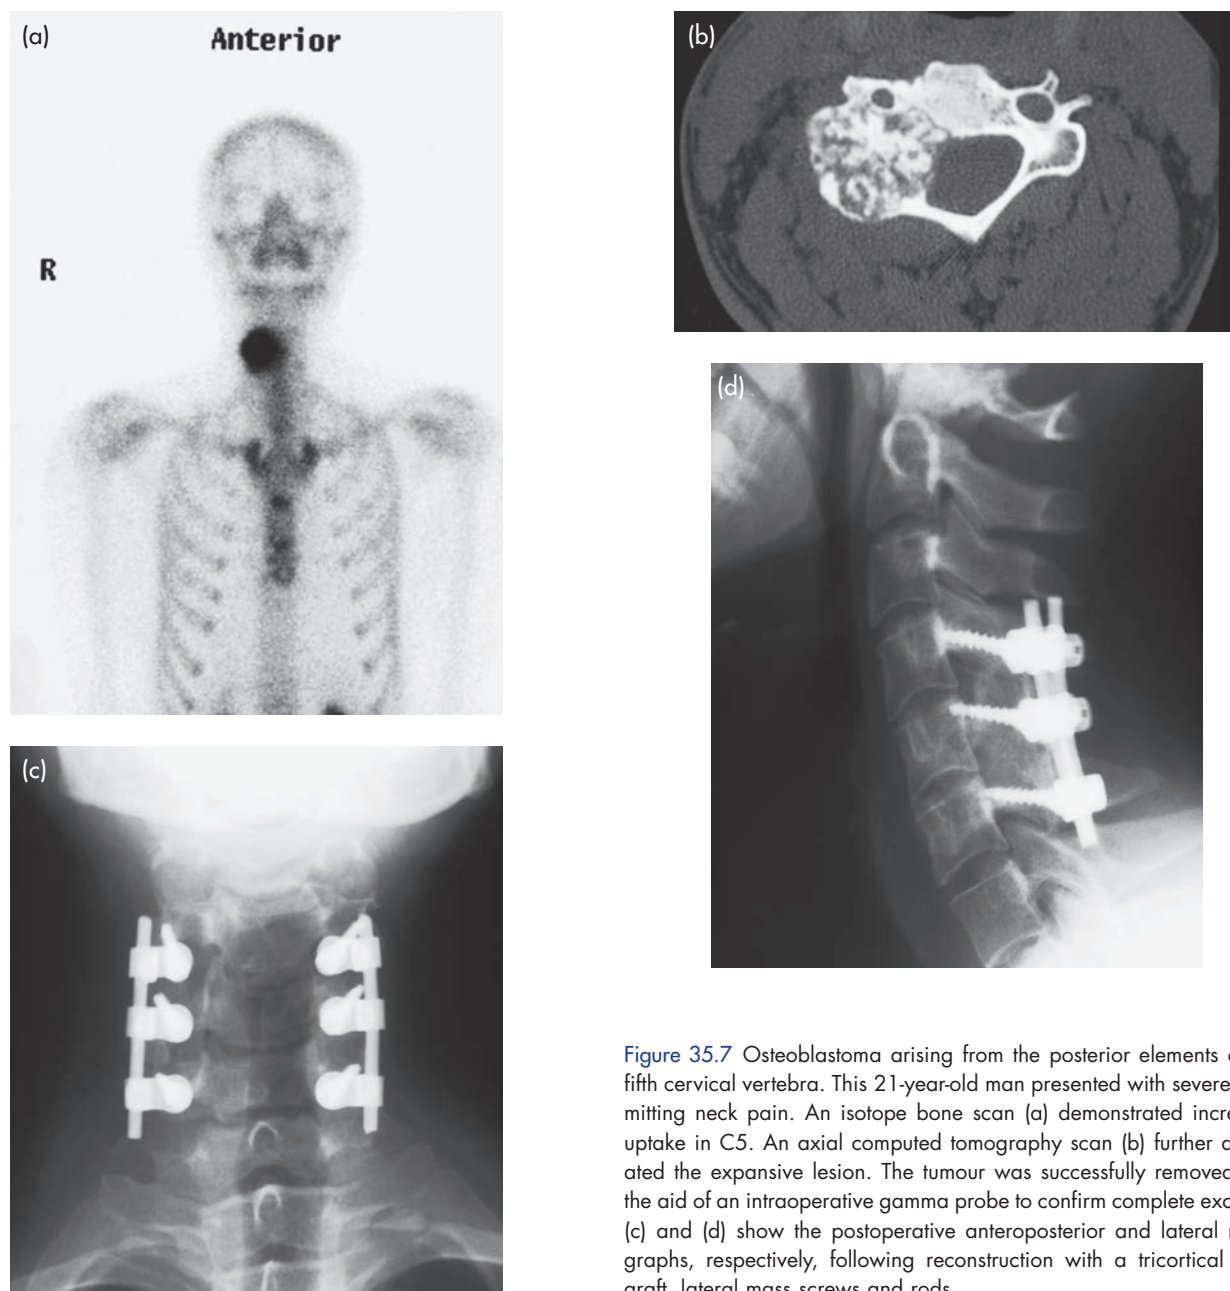

Figure 35.7 Osteoblastoma arising from the posterior elements of the fifth cervical vertebra. This 21-year-old man presented with severe unremitting neck pain. An isotope bone scan (a) demonstrated increased uptake in C5. An axial computed tomography scan (b) further delineated the expansive lesion. The tumour was successfully removed with the aid of an intraoperative gamma probe to confirm complete excision. (c) and (d) show the postoperative anteroposterior and lateral radiographs, respectively, following reconstruction with a tricortical bone graft, lateral mass screws and rods.

Table 35.10 Recommendations for spinal surgery in rheumatoid arthritis.

Atlantoaxial subluxation (AAS) with a posterior atlantodental interval (PADI) of 14 mm or less
AAS with at least 5 mm of basilar invagination
Subaxial subluxation with a sagittal canal diameter of 14 mm or less

SPINAL DEFORMITY

Spinal deformity may be categorised into a coronal plane deformity (scoliosis) or a sagittal plane deformity (kyphosis

and lordosis.). Further classification may be made on the basis of aetiology into congenital, neuromuscular, idiopathic or syndromic. Appropriate radiographs for the assessment of scoliosis include a full posteroanterior and lateral standing spine. When surgery is contemplated, supine lateral bending radiographs are performed to assess the flexibility of the curve(s). Curve magnitude is measured in degrees and known as the Cobb angle. The criterion for diagnosis of scoliosis is a Cobb angle of 10° or more. The causes of scoliosis are given in Table 35.11.

Congenital scoliosis

This is caused by vertebral anomalies that produce a frontal plane growth asymmetry. The anomalies are present at birth,

Figure 35.8 Haemangioendothelioma arising from the body of the 11th thoracic vertebra. This 34-year-old man presented with signs of spinal cord compression and severe pain in the lower thoracic region. The anteroposterior radiograph (a) demonstrated loss of both pedicles at T11. Axial computed tomography (b) confirmed a lytic lesion. Magnetic resonance imaging (c) demonstrated spinal cord compression on the axial T1-weighted scan. The patient underwent a staged posterior stabilisation, total en bloc spondylectomy and anterior column reconstruction. (d) and (e) show the postoperative anteroposterior and lateral radiographs, respectively.

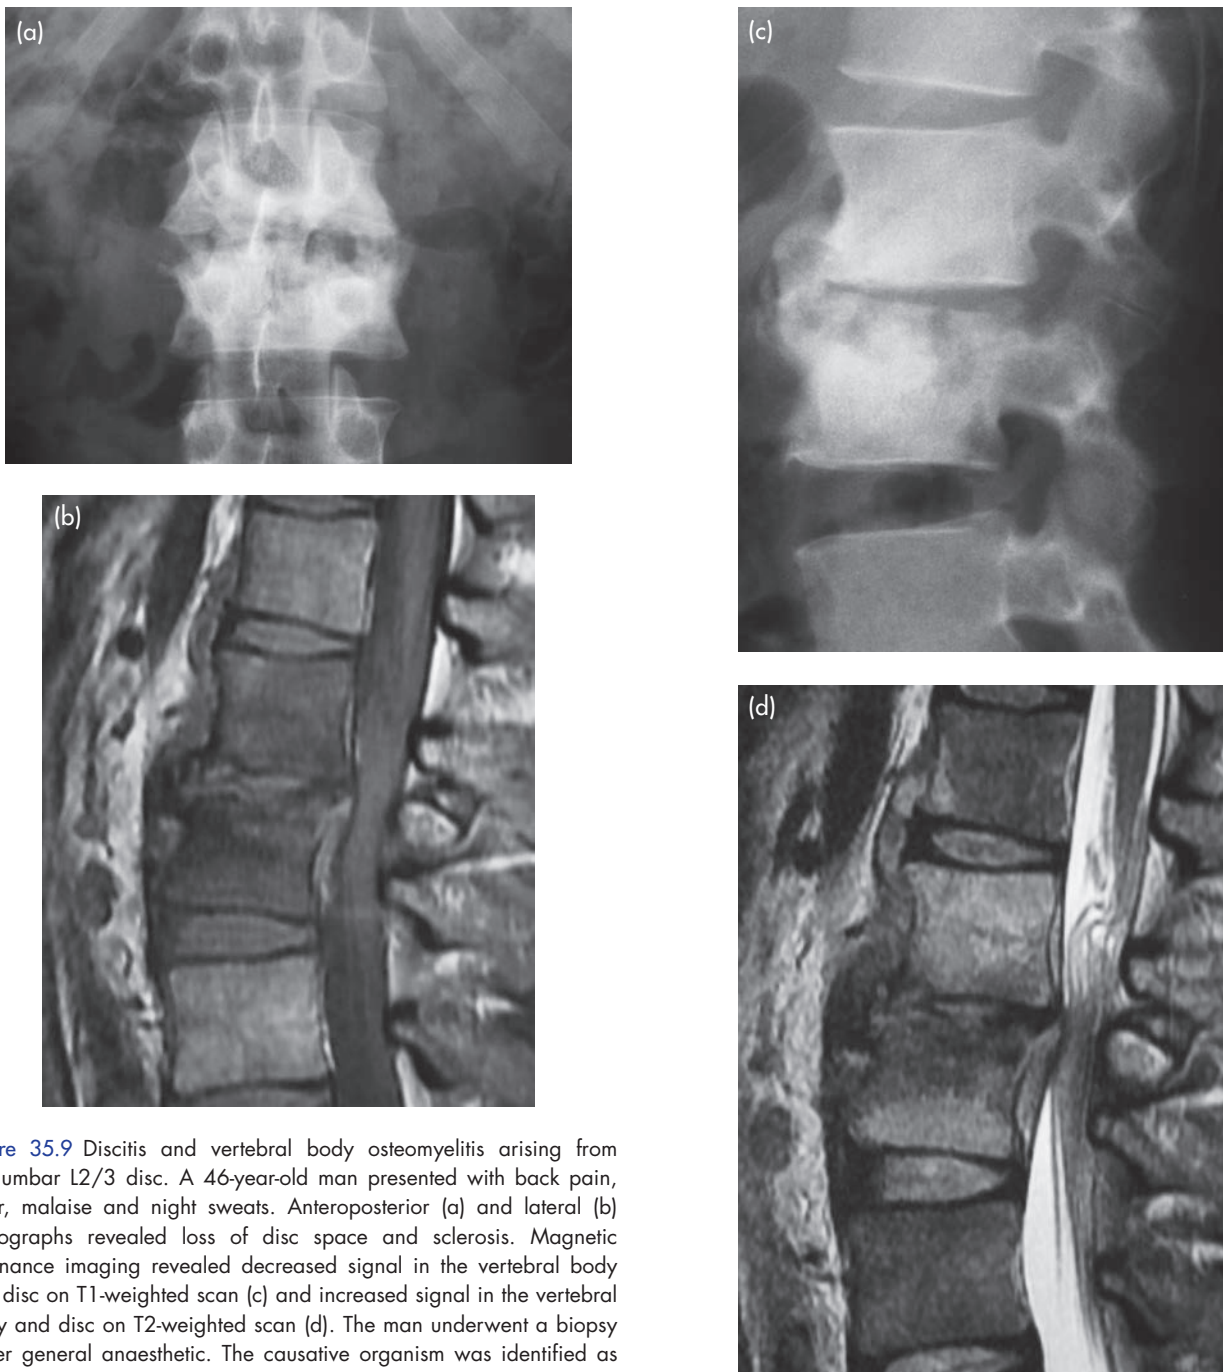

Figure 35.9 Discitis and vertebral body osteomyelitis arising from the lumbar L2/3 disc. A 46-year-old man presented with back pain, fever, malaise and night sweats. Anteroposterior (a) and lateral (b) radiographs revealed loss of disc space and sclerosis. Magnetic resonance imaging revealed decreased signal in the vertebral body and disc on T1-weighted scan (c) and increased signal in the vertebral body and disc on T2-weighted scan (d). The man underwent a biopsy under general anaesthetic. The causative organism was identified as *Staphylococcus aureus*. He was successfully treated with intravenous antibiotics and an orthosis.

Table 35.11 Aetiology of scoliosis.

Congenital
Neuromuscular
Idiopathic
Syndrome related

but the curvature may take years to be clinically evident. Close observation of spinal growth is required until skeletal maturity is reached. Brace treatment is ineffective for the primary structural curves, which are often short and rigid, but it may have a role in the control of compensatory curves. For progressive curves, surgical options include growing rod constructs, hemivertebra excision, correction and fusion or posterior instrumented correction and fusion.

Figure 35.10 Cervical osteotomy for correction of cervicothoracic kyphosis. Planned resection lateral view for closing wedge osteotomy (left) and lateral view after closure of the osteotomy (right).

Neuromuscular scoliosis

This may be due to neuropathic disorders, such as cerebral palsy, spinocerebellar degeneration, syringomyelia, quadriplegia, spinal muscular atrophy and poliomyelitis, or myopathic disorders, such as Duchenne muscular dystrophy and myotonic dystrophy. There is good evidence that stabilisation of the spine in children with Duchenne muscular dystrophy who are able to walk (before respiratory compromise is too severe to preclude a general anaesthetic), may increase their lifespan by several years.

Idiopathic scoliosis

Idiopathic scoliosis can be divided into early onset (before eight years of age) (Figure 35.11) and late onset (after eight years of age; typical adolescent idiopathic scoliosis) (Figure 35.12). The distinction is important, as the number of alveoli in the lung does not increase after the age of eight years. Patients with severe curves in the early-onset group may develop cor pulmonale and right ventricular failure resulting in premature death. Adolescent idiopathic scoliosis is associated with a normal or near-normal life expectancy.

The prevalence of curves with a Cobb angle greater than 10° is between 0.5 and 3 per cent. The prevalence of curves greater than 30° is between 1.5 and 3 per 1000. Risk factors for progression include female gender, remaining skeletal growth, curve location and curve magnitude. Not all curves stabilise when skeletal maturity is reached. In long-term studies, 68 per cent experienced curve progression; the most marked progression of 1° per year was observed in thoracic curves between 50 and 75° .

Idiopathic curves of less than 25° are monitored with clinical and radiographic examination. In growing children (pre-menarchal) with curves between 20 and 29° , a brace may be indicated. Bracing is used to prevent curve progression and generally does not lead to permanent curve improvement. Curves beyond 45° are not amenable to brace treatment.

Surgery in the form of corrective instrumentation and spinal fusion is indicated for curve progression beyond 40° ,

truncal imbalance and unacceptable cosmesis. During surgery, continuous electrical spinal cord monitoring is used in the form of somatosensory-evoked potentials and, more recently, motor-evoked potentials to minimise the risk of neurological damage. The risk of neurological injury is 0.4 per cent (1:250) (Summary box 35.8).

Summary box 35.8

Spinal deformity

- Congenital scoliosis: rigid curves do not respond to brace treatment
- Neuromuscular scoliosis: timely surgery may prolong life
- Early onset scoliosis: (<8 years old) has potential to impair lung function

Scheuermann's kyphosis

In this condition typically there is wedging of the seventh to tenth thoracic vertebrae. The patient presents with backache. The incidence has been estimated at 1–8 per cent of the population, and is more common in males. Physiotherapy may be useful. Bracing for skeletally immature patients with kyphosis up to 65° may be effective in arresting progression. Indications for surgery include pain (apical or low back pain produced by compensatory hyperlordosis), progressive deformity greater than 70° , unacceptable cosmesis, and neurological and cardiac pulmonary compromise. If surgery is contemplated, it may require anterior release followed by posterior correction and fusion. Increasingly, posterior chevron osteotomies carried out at the time of posterior instrumentation may prevent the need for the initial anterior release.

DEVELOPMENTAL ABNORMALITIES

Developmental abnormalities of the spine and spinal cord can be divided into primary bony disorders (e.g. congenital scoliosis as discussed above) and primary neurological disorders (e.g. spina bifida, Arnold–Chiari malformation and spinal dysraphism).

Spina bifida

Spinal bifida is caused by a failure of fusion of the vertebral arches and possibly the underlying neural tube. Spina bifida cystica has an incidence of 1:300 live births and is associated with hydrocephalus. It is now decreasing as a consequence of folic acid supplementation, antenatal ultrasound and the measurement of alpha-fetoprotein levels. There are two basic types:

- **Meningocele:** The meninges herniate through the bony defect and are covered by skin.
- **Myelomeningocele:** The roof of the defect is formed by exposed neural tissue with 75 per cent of cases developing hydrocephalus.

A meningocele with good-quality skin over the defect may be treated conservatively. A meningocele with a more prominent sac can be excised at 3–6 months. The management of myelomeningocele is more controversial. Enthusiasm for closing all defects has been replaced by a more selective approach with the recognition that it was inappropriate to operate on children with

Figure 35.11 Early-onset idiopathic scoliosis. The anteroposterior standing radiograph (a) demonstrates a Cobb angle of 98° and dextrocardia. This 34-month-old boy underwent a convex hemiepiphysodesis over the apical four discs (b), followed by posterior Luque trolley instrumentation without fusion to correct the spinal deformity and allow continued growth (c and d).

Hans Chiari, 1851–1916, an Austrian, Professor of Pathological Anatomy at German University in Prague, first described these hindbrain malformations between 1891 and 1896 as four types.

Julius Arnold, 1835–1915, German pathologist born in Zurich, Professor of Pathological Anatomy, Heidelberg, Germany, described this malformation in an infant in 1894. In 1907 Dr Arnold's students coined the eponym 'Arnold-Chiari malformation' in their honour. Some refer this condition specifically to the Type 2 variety.

severe hydrocephalus, a large open defect and no distal neurological function. The majority of these children die in their first year if closure is not attempted. With antibiotics, early surgical closure and shunts to prevent hydrocephalus, half the children who survive the first 24 hours will reach school age, but long-term problems remain, including skin, neuromuscular scoliosis, bone and joint deformity and the complications associated with a neuropathic bladder.

Figure 35.12 Late-onset idiopathic scoliosis. This 15-year-old girl had a progressive scoliosis with unacceptable cosmesis. The standing radiograph (a) demonstrated a right thoracic curve with a Cobb angle of 59° and a left thoracolumbar curve of 75°. Both curves were flexible on supine bending films. She underwent a posterior correction and instrumented fusion from T4 to L4 (b).

Arnold–Chiari malformation

Arnold–Chiari malformation occurs when the medulla oblongata and the cerebellar tonsils extend through the foramen magnum into the cervical spinal canal, causing pressure on the lower medulla. Hydrocephalus and impaired neurological function are common, and there is a strong association with spina bifida and syringomyelia. Symptoms may include headache, vomiting, visual disturbances, mental impairment, cerebellar ataxia, sensory disturbances or paralysis. Management consists of decompressing the foramen magnum and, usually, the posterior arch of the atlas to restore normal cerebrospinal fluid flow.

Spinal dysraphism

This is a group of disorders arising from abnormal embryological formation of tissues: all are associated with a progressive neurological deficit as the result of cord tethering and traction or cord compression. There is a strong association with spina bifida.

In diastematomyelia, there is an abnormal bony or cartilaginous spur projecting across the middle of the vertebral canal, dividing the dural tube and spinal cord in two. Between 50 and 70 per cent of patients have a skin naevus, dimple or hairy patch when the spine is examined. Surgical release of the tethering has variable results.

Syringomyelia

Patients may present with sensory disturbance, weakness of the hands, loss of pain and temperature sensation or progressive kyphoscoliosis. It is associated with Arnold–Chiari malformation and spinal cord tumours. Where syringomyelia is associated with an Arnold–Chiari malformation and scoliosis, a posterior cranial

fossa decompression should be carried out first to resolve the syringomyelia. The scoliosis may then be corrected at a later date.

METABOLIC BONE DISEASES AFFECTING THE SPINE

Osteoporosis

Patients with osteoporosis may present with pain after minimal trauma or loss of height and an exaggerated thoracic kyphosis. Medications used to prevent and treat osteoporosis include the bisphosphonates (alendronate, risedronate), oestrogen or hormone replacement therapy and calcitonin.

Patients with painful thoracic fractures may be treated with short-term bed rest, analgesics and a spinal orthosis. If the back is still painful 6 weeks after the injury, patients may be considered for vertebroplasty or kyphoplasty. Vertebroplasty involves the injection of polymethyl methacrylate (PMMA) bone cement under pressure into the vertebral body under fluoroscopic guidance. The goal of the procedure is to stabilise the spine and decrease pain associated with compression fractures.

Kyphoplasty, on the other hand, involves inserting bilateral bone tamps with balloons into the vertebral body. These are inflated under fluoroscopic control with the bone tamp re-expanding the body, elevating the end-plates to reduce the fracture deformity. The balloons are then deflated and removed, and PMMA is placed into the cavity created by the balloons. The goals of kyphoplasty are spinal stabilisation, pain relief and restoration of vertebral body height. Significant complications have been reported, including nerve root injury and spinal cord injury resulting from cement extravasation along with cement embolism, infection and hypotension.

CHAPTER 36

Upper limb – pathology, assessment and management

LEARNING OBJECTIVES

To understand:

- Anatomy and physiology relevant to upper limb pathology

To be able to explain:

- The diagnosis and treatment of common upper limb conditions

SHOULDER GIRDLE

Anatomy and function

The shoulder moves around the sternoclavicular joint, controlled and limited by muscles crossing between the thorax, scapula and humerus. The glenohumeral joint is controlled by the deltoid and rotator cuff muscles (subscapularis, supraspinatus, infraspinatus and teres minor). The scapula is integral to shoulder motion by both gliding and rotating on the posterior surface of the thorax (Figure 36.1).

Figure 36.1 Relative motion of the elements of the shoulder girdle.

Congenital abnormalities

Sprengel's shoulder

The most common congenital abnormality is due to abnormal scapular descent from its embryonic midcervical position. Presentation is a high, small, rotated scapula with connection to the cervical spine by a bony bar, fibrous band or an omovertebral body (Figure 36.2). Other congenital deformities are rib abnormalities, and cervical or thoracic scoliosis including Klippel–Feil syndrome (congenital fusion of cervical vertebrae).

Figure 36.2 Sprengel's shoulder (right) of a four-year-old girl.

Otto Gerhard Karl Sprengel, 1852–1915, surgeon, Grossherzogliches Krankenhaus (the Grand Ducal Hospital), Brunswick, Germany, described congenital high scapula in 1891.

Maurice Kippel, 1858–1942, neurologist, Hôpital Tenon, Paris, France.

André Feil, 1889–?, neurologist, Paris, France.

Kippel and Feil described this condition in a joint paper in 1912.

Charles Sumner Neer II, orthopaedic surgeon, Columbia-Presbyterian Medical Center, New York, NY, USA.

Acquired abnormalities

History

Patients usually associate the onset of their symptoms with an unusual event (trauma or excessive activity) even though the causation may not be as clear as the patient thinks. Even so, the onset (sudden or gradual) and duration are important as is the age of the patient and their occupation. Pain presenting in the shoulder (or anywhere in the upper limb) can arise from the nerves of the neck, so the history should include questions about neck problems.

Examination

If the patient can localise the source of the pain to an exact point in the shoulder, then the problem is unlikely to be referred from the neck. Tests for inflammation and impingement involve trying to reproduce the pain by loading the limb in the position which creates the problem (Hawkin's test for impingement, see Figure 36.3). Tests for tears in structures such as the rotator cuff look specifically for weakness, while apprehension tests check for instability (such as shoulder dislocation).

Investigations

X-rays are only of limited value because most lesions in the shoulder involve damage to the soft tissues. However, a reduced subacromial space and an acromial spur may be clearly visible in rotator cuff damage (Figure 36.4).

Figure 36.3 Hawkin's impingement test. Impingement pain is reproduced when the shoulder is internally rotated with 90° of forward flexion, thereby locating the greater tuberosity underneath the acromion.

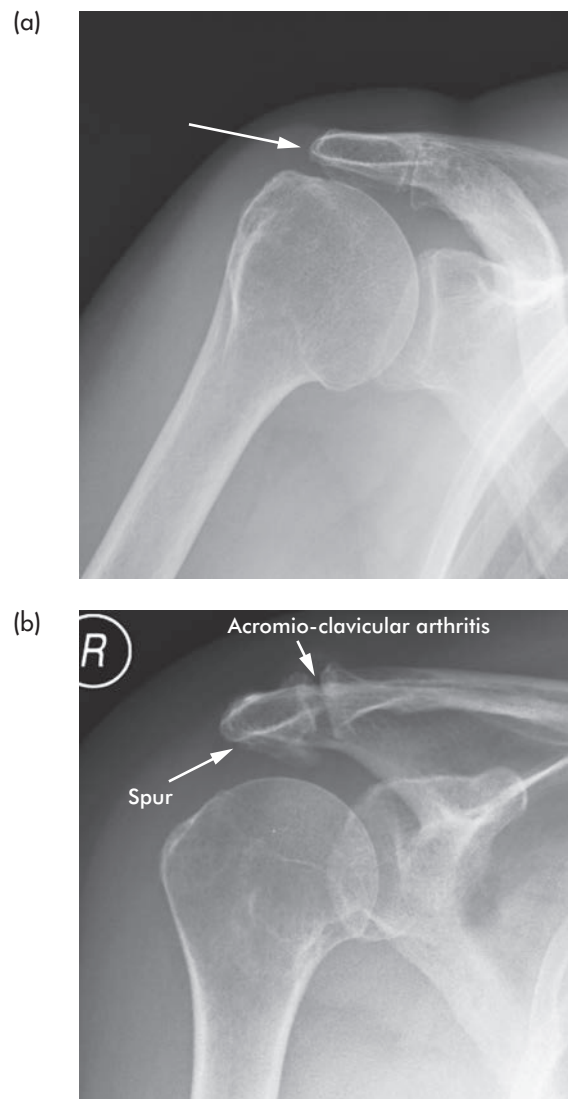

Figure 36.4 (a) Radiograph showing sclerosis on the undersurface of the acromion and the greater tuberosity with reduced subacromial space. (b) Radiograph showing an acromial spur and arthritis of the acromioclavicular joint.

Both ultrasound and magnetic resonance imaging (MRI) allow the integrity and health of the rotator cuff to be checked, and the integrity of the labrum of the glenohumeral joint (Figure 36.5).

Local anaesthetic injections may help localise the source of inflammation and pain.

Rotator cuff tendonitis

The rotator cuff moves in a confined space between the humeral head, the acromion and the coracoacromial (CA) ligament. Even a trivial injury can start a progression of inflammation, swelling and pain, which in turn causes impingement. The impingement then causes further swelling and pain and a vicious circle is set up. The likelihood of tendonitis developing is increased by a beak of bone which tends to appear beneath the acromion with age (Figure 36.6). The result is a painful arc

Figure 36.5 Magnetic resonance imaging showing a retracted cuff tear.

of movement for the patient which corresponds to the position where the inflamed segment of the supraspinatus tendon jams under the subacromial beak. The examiner may find that although the patient cannot lift their arm through this segment (because of the pain), passively lifting the arm for the patient enables them to continue with pain-free movement once the impingement is past (Figure 36.7).

Treatment

Injection of steroid into the inflamed area may break the cycle of inflammation and impingement (Figure 36.8), but arthroscopic removal of the subacromial beak and of the CA ligament (if it is impinging) should give good relief of symptoms (Figure 36.9) (Summary boxes 36.1 and 36.2).

Summary box 36.1

Rotator cuff tendonitis

- Tendonitis produces weakness secondary to pain (often a painful arc)
- A tendon tear produces weakness which is only secondarily painful
- Injection of local anaesthetic can be diagnostic

Summary box 36.2

Treatment of subacromial impingement

- Non-operative treatment includes injections
- Surgery indicated if symptoms persist beyond six months
- Surgery decompresses the rotator cuff

Rotator cuff tears

The rotator cuff also has a poor blood supply and is subject to degenerative changes which weaken it with age. This means that tears are more common in the elderly and at any age are unlikely to repair spontaneously. Tears usually begin at the anterolateral edge of the supraspinatus, and progress posteriorly to involve the infraspinatus and teres minor, tendons. This creates a bare area over the greater tuberosity, as the torn cuff retracts medially (Figure 36.10).

History

In the younger patient the onset is often relatively major trauma, e.g. saving a fall by hanging onto the rung of a ladder, but in the elderly the onset may follow a painful period of tendonitis or even apparently occur spontaneously.

Examination

The patient may have a mixed picture of tendonitis and of a tear, but if the pain is removed by injection of local anaesthetic the weakness will persist. Symptomatic tears are associated with pain, weakness, limited active abduction, cuff muscle wasting and hunching of the shoulder when attempting abduction (Figure 36.11).

Investigation

Tears are classified as small (less than 1 cm), intermediate (2–4 cm) and large (more than 5 cm).

Treatment

Treatment depends on the patient's age, lifestyle and severity of symptoms. Arthroscopic or open repair with subacromial decompression can be considered for all tears, but is likely to give a much better and useful result in the young than in the old. It may not be possible to suture large tears due to loss of muscle contractility, and then complex surgery, e.g. tendon transfers, patch grafts or reverse joint replacement (Figure 36.12) will need to be considered (Summary box 36.3).

Figure 36.6 The three most common acromial morphologies.

Figure 36.7 Arcs of shoulder girdle motion with subacromial impingement pain between 60 and 120° of abduction, and acromioclavicular joint pain between 170 and 180°.

Figure 36.8 Technique of administering an injection into the subacromial bursa.

The pathognomonic sign is a loss of external rotation. X-rays are normal.

Treatment

The clinical course can run over one to three years and is divided into painful, stiffening and thawing phases. If untreated, frozen shoulder will usually resolve, and the majority of patients are left with no functional problems. In the first phase of the condition, treatment is pain relief. Corticosteroids can also be injected locally. Despite the pain, the patient should be encouraged to perform as much active and passive movement as they can. Surgical release of the tight capsule can produce some pain relief in the early stages and is also indicated for prolonged stiffness.

Summary box 36.3

Rotator cuff tears

- Occur in older age group
- Twenty to forty per cent of 40–50 year olds have asymptomatic rotator cuff tears
- Fifty per cent of 70 year olds have an asymptomatic tear
- Subacromial decompression is important for pain relief following cuff repair
- Acute tears present with little pain but profound weakness
- Early repair gives good results

Frozen shoulder (adhesive capsulitis, contracted shoulder)

This is an idiopathic painful and stiff condition usually affecting females in their fifties. It is also associated with diabetes, heart or thyroid disease.

History and examination

Frozen shoulder is characterised by the sudden onset of severe pain and may follow minor trauma. The differential diagnoses are infection, fractures and rotator cuff tears. Initially there is severe pain but this improves with time; however, there is global loss of active and passive movements limited by pain.

Figure 36.9 (a) Arthroscopic view of an acromial spur. (b) Arthroscopic view after the acromial spur has been removed and the cuff decompressed.

Figure 36.10 Various stages of rotator cuff tear. Initial partial-thickness tears have the potential to progress to full thickness and retracted tears.

Figure 36.11 A 75-year-old man with a >5 cm retracted cuff tear attempting to abduct his shoulder, which is limited, by lack of balanced motor power, below 60°.

Figure 36.12 Reverse geometry total shoulder replacement.

Manipulation under anaesthesia or arthroscopic saline distension of the joint with release of the rotator cuff interval is also felt to reduce pain and improve mobility (Summary box 36.4).

Summary box 36.4

Frozen shoulder (adhesive capsulitis)

- Predominantly occurs in females in their fifties
- Spontaneous onset
- Produces severe pain followed by reduced shoulder motion
- Spontaneous resolution can occur over one to three years
- Differential diagnoses: calcific tendonitis and rotator cuff tear
- Injections, distension with saline and surgical release may all help

Calcific tendonitis

Calcium deposition within the supraspinatus tendon is believed to be part of a degenerative process, or the consequence of a partial degenerative tear of the tendon.

History and examination

There is severe, rapid onset shoulder pain with painful restricted motion. However, in contrast to adhesive capsulitis, external rotation is possible. Subacromial calcific deposits can be seen on plain radiographs (Figure 36.13).

Treatment

Subacromial corticosteroid injections may help. The condition is often self-limiting, with resorption of the calcium deposits. Surgery for resistant cases includes arthroscopic or open subacromial decompression and excision of the calcific deposits.

Arthritis of the shoulder

Rheumatoid arthritis

The glenohumeral joint is commonly involved in rheumatoid arthritis (Figure 36.14). Usually, there is osteoporosis, destruction of the articular cartilage and synovial proliferation with

Figure 36.13 Radiograph demonstrating calcific tendonitis.

Figure 36.14 Rheumatoid arthritis of the shoulder.

pannus formation. The rotator cuff is weakened and frequently tears. Arthroscopic synovectomy may slow the progress of the joint destruction and lead to a reduction in pain and improvement in range of movement. Intra-articular steroid injections may also be helpful. Shoulder replacement is complicated by poor bone stock and damage to the stabilising structures around the shoulder, especially the rotator cuff. The patient should only expect a reduction in pain. Any increase in range of movement is a bonus (Summary box 36.5).

Summary box 36.5

Shoulder problems in rheumatoid arthritis

- Arthroscopic synovectomy is effective
- Rotator cuff tears are common
- Glenohumeral joint replacement improves pain but motion to a lesser degree

Osteoarthritis of the shoulder

Glenohumeral joint osteoarthritis is either primary (Figure 36.15), secondary to trauma (Figure 36.16) or end-stage rotator cuff disease, i.e. cuff arthropathy (Figure 36.17).

Treatment

If medical treatment has failed, the surgical options are arthroscopic debridement or joint arthroplasty. Debridement is not predictable, but both total shoulder replacement (Figure 36.18) and hemiarthroplasty (Figure 36.19) have good results in appropriate patients. A standard total shoulder arthroplasty can be performed if the rotator cuff is intact. However, in most osteoarthritis patients and all patients with cuff tear arthropathy, the cuff is deficient, and either a hemiarthroplasty or a reverse polarity total shoulder arthroplasty (Figure 36.12) should be used. Shoulder arthroplasty is an effective pain-relieving procedure, but less predictable in restoring motion, especially above shoulder level.

Figure 36.15 Osteoarthritis of the glenohumeral joint.

Figure 36.16 Post-traumatic arthritis with malunion of the proximal humerus, collapse of the humeral head, subchondral sclerosis and osteophytes.

Figure 36.17 A massive cuff tear that has led to superior migration of the humeral head and secondary osteoarthritis of the glenohumeral joint.

Figure 36.18 Total shoulder replacement done for osteoarthritis. An intact rotator cuff is essential.

Arthrodesis of the joint is an alternative in younger patients with a history of sepsis or neurological problems (Figure 36.20). Patients retain a moderate range of movement at the shoulder, as a result of scapulothoracic motion (Summary box 36.6).

Summary box 36.6

Arthritis of the shoulder

- Severe cases are treated with hemiarthroplasty or total shoulder arthroplasty
- Total shoulder replacements should not be performed if the rotator cuff is deficient
- Pain relief is good following arthroplasty though improvement in range of motion is less predictable
- Glenohumeral arthrodesis is an option in the young or those with a history of sepsis
- Post-arthrodesis motion is fair but is entirely scapulothoracic

Acromioclavicular joint arthritis

Acromioclavicular joint (ACJ) arthritis is common and is often asymptomatic, noted as an incidental finding on x-ray (Figure 36.4b). Symptoms typically arise in males aged 20–50 years. Inferior osteophytes can impinge on the underlying rotator cuff.

History and examination

There is frequently a history of trauma to the ACJ. Pain is activity related. There is prominence of the lateral end of the clavicle. The joint line is tender. Flexing and adducting the arm to place the hand behind the opposite shoulder reproduces pain. If symptoms are related to inferior osteophytes, impingement symptoms and signs are also present.

Figure 36.19 Shoulder hemiarthroplasty is performed for arthritis if there is a deficient rotator cuff.

Treatment

An intra-articular corticosteroid injection will usually help. Surgery involves arthroscopic or open excision of the lateral 0.5–1 cm of the clavicle (Figure 36.21). This gives good pain relief. In patients with symptoms, which are predominantly impingement, arthroscopic removal of the osteophytes should be performed (Summary box 36.7).

Figure 36.20 Arthrodesis of the shoulder.

Figure 36.21 Arthroscopic end-on view of the clavicle after excision of its distal end.

Summary box 36.7

Acromioclavicular joint problems

- Acromioclavicular joint arthritis is common and may be asymptomatic
- It becomes symptomatic secondary to trauma or repetitive overload
- Inferior clavicular osteophytes can impinge on the cuff
- Intra-articular steroid and local anaesthetic injection may relieve symptoms
- Excision of the lateral end of the clavicle gives good results

Long head of biceps tendon rupture

Rupture of the long head of biceps usually occurs in the elderly, and is due to abrasion of the tendon in the bicipital groove. It is associated with rotator cuff tears. Most patients present with few symptoms, although they often seek advice because of the bulge they notice in their arm.

History and examination

Patients feel a sense of 'something giving way' in front of the shoulder. The upper arm is bruised, and elbow flexion produces a swelling in the front and middle of the arm. The lump will be

permanent and is initially tender. Power is diminished (Figure 36.22).

Treatment

Reassurance that pain and bruising will resolve is sufficient. Power improves over several months and surgery (biceps tenodesis) is not needed.

Dislocation of the shoulder and instability of the glenohumeral joint

Three broad groups of shoulder instability exist:

- Traumatic: unidirectional; involuntary; surgery is usually successful
- Atraumatic: multidirectional, painful; involuntary; responds to surgery
- Habitual: voluntary with ligament laxity, painless; surgery usually contraindicated.

Recurrent traumatic instability

History

Traumatic shoulder dislocation is the most common of all dislocations, usually first presenting in patients under 25 years of age. Usually, the shoulder dislocates anteroinferiorly. Initially, there is a notable traumatic event. Subsequent dislocations require less force. The shoulder may sublux or actually dislocate (complete separation of the joint surfaces).

Examination

On examination the shoulder has a full range of motion, but with forced abduction and external rotation, the patient experiences apprehension (a sense of impending doom!) (Figure 36.23).

Figure 36.22 Bruising and change in the upper arm shape due to rupture of the long head of biceps.

Figure 36.23 Apprehension test for anterior instability.

Investigations

On ultrasound or MR arthrogram, detachment of the antero-inferior labrum (Bankart lesion) and damage to the humeral head (Hill–Sachs lesion) can often be seen (Figures 36.24, 36.25 and 36.26).

Treatment

The relative indications for surgery are repeated dislocations which are interfering with the patient's quality of life. An absolute indication for surgery is when dislocations occur when the patient is asleep. Anterior instability requires arthroscopic or open repair of the Bankart defect with tightening of the capsule, and produces good results in 90–95 per cent of patients. Bony defects may have to be grafted. For the less common recurrent posterior instability, repair of the damaged labrum and tightening of the posterior capsule is needed (Summary box 36.8).

Summary box 36.8

Recurrent traumatic shoulder instability

- An appreciable force leads to the first dislocation or subluxation
- Subsequent dislocations/subluxations require less force
- The most common direction of dislocation is antero-inferior
- There is a positive apprehension sign
- Surgical treatment repairs the labral lesion and tightens the capsule

Figure 36.25 An end-on view of the glenoid labrum, demonstrating antero-inferior labral detachment (red) with the rotator cuff muscles (brown), long head of biceps tendon and labrum (blue).

Posterior dislocation of the shoulder

This is a rare event but is easy to miss. The clue is in the history as the patient will have either had an electric shock, an epileptic fit, or have been subject to severe restraint when their arm has been forced up their back (a half-nelson).

The patient will be in severe pain and if they are psychotic (and this is why they are being restrained) then they will be difficult to examine. For the same reason, the radiographer may only be able to get an anteroposterior view of the shoulder, and on this view, the shoulder looks normal to the unwary (Figure 36.27). It is the high 'index of suspicion' from the history which gives the best chance of making the diagnosis.

Treatment

This dislocation is frequently difficult to reduce as the posterior margin of the acromion is embedded in the humeral head, so that open reduction is needed.

Atraumatic instability

History

There is usually no history of an initial injury. Instability may be multidirectional and the shoulder usually only subluxes rather than dislocates. The patient is often able to reduce the shoulder without assistance.

Figure 36.24 Schematic representation of Bankart's lesion that forms a spectrum of pathology from minor labral detachment (B) to large detachments with glenoid rim fractures (bony Bankart; E).

Figure 36.26 (a) Magnetic resonance arthrogram showing anterior Bankart lesion. (b) Magnetic resonance arthrogram showing posterior labral injury.

Examination

Generalised ligament laxity is common. Apprehension tests are positive, but often in more than one direction. Anterior and posterior drawing of the humeral head allows laxity to be tested (Figure 36.28).

Treatment

Specialist physiotherapy should be tried first in these patients, aiming to improve both the proprioception and strength of the muscles around the shoulder. If this fails then surgery is needed to perform capsular tightening.

Habitual dislocation

Habitual dislocators are patients who can sublux the shoulder at will, either anteroinferiorly or posteriorly. The manoeuvre is painless. Patients have generalised joint laxity and may sublux the shoulder as a 'party trick'.

Patients should be told to stop subluxing the shoulder, and the capsule will tighten naturally. Surgery is associated with high failure rate and should be avoided.

DISORDERS OF THE ELBOW

Anatomy and function

The elbow joint allows flexion and extension as well as making up the proximal part of the radioulnar joint which permits

Figure 36.27 Posterior dislocation of the shoulder. (a) Anteroposterior view; (b) origin of the light bulb sign; (c) axial projection demonstrating how much easier it is to visualise the injury on this view; (d) axial projection highlighting this point and further demonstrating the impacted fracture in the humeral head, or Hill-Sachs lesion.

Figure 36.28 Generalised laxity can be appreciated by drawing the humeral head in anterior and posterior direction. A sulcus will be produced under the acromion if the humerus is drawn inferiorly (sulcus sign).

pronation and supination of the forearm. The brachial artery passes immediately in front of the joint, while the ulna nerve passes lateral to the medial epicondyle immediately behind it.

Tennis elbow (lateral epicondylitis) and golfer's elbow (medial epicondylitis)

These are discussed in Chapter 34.

Arthritis of the elbow

Rheumatoid arthritis

Surgery is required, especially in end-stage disease. Arthroscopic or open radial head excision and synovectomy is effective for painful, restricted pronation and supination. Elbow arthroplasty is effective for pain relief and functional restoration (Figure 36.29).

Figure 36.29 Typical end stage unstable and destroyed rheumatoid elbow.

Figure 36.30 (a and b) X-rays showing osteoarthritis of the elbow joint.

Osteoarthritis

Osteoarthritis of the elbow is usually primary (Figure 36.30) or secondary to trauma.

History

Typical patients are middle-aged males in manual occupations. Symptoms are pain, locking, crepitus and painful motion with loss of extension. Ulnar nerve entrapment symptoms may be present.

Examination

There is usually loss of extension and restriction of flexion. Pronation and supination tends to be spared in comparison with rheumatoid arthritis.

Treatment

Surgery should be considered only if medical treatment fails. Arthrodesis is the treatment of choice for those performing heavy manual work, as a joint replacement will not survive long under heavy loading. Surgical debridement alleviates pain

and increases range of motion in earlier stages. Prosthetic joint arthroplasty provides a more predictable symptomatic relief (Figures 36.31 and 36.32) (Summary box 36.9).

Summary box 36.9

Arthritis of the elbow

- Excision of the radial head improves pain and pronation in rheumatoid arthritis
- Total elbow replacement gives good results in rheumatoid and low demand patients
- Arthrodesis is the better option in a high demand manual labourer

Figure 36.32 Ankylosed elbow after tuberculosis.

Loose bodies in the elbow

The common causes are osteoarthritis, osteochondritis dissecans in the young (Figure 36.33) and synovial chondromatosis (Figure 36.34). Patients describe sudden pain and locking, and need to manipulate the elbow for relief. Plain radiographs will usually confirm the diagnosis (Figure 36.35). Arthroscopic clearance of the joint produces good results (Figure 36.36).

Olecranon bursitis

This is a relatively common disorder where the elbow becomes red, warm, swollen and painful. Initially, septic arthritis may be suspected. However, on examination, signs and symptoms are confined to the back of the elbow (Figure 36.37) and movement within an arc of 30–130° is possible. Most cases settle with anti-inflammatories. If the patient is pyrexial, antibiotics should be given. Formal drainage of the bursa is indicated if purulent material is present.

Chronic bursitis may be associated with calcific nodules of the bursal lining (Figure 36.38). These can be excised if they prove troublesome.

Ulnar nerve compression

Compression of the ulnar nerves occurs around the elbow at the junction of the arcade of Struthers and also the medial intermuscular septum as the nerve passes into the posterior compartment of the distal humerus. It can also occur under the medial epicondyle or as the nerve passes between the heads of the flexor carpi ulnaris (Figure 36.39).

History and examination

Patients describe tingling/numbness in little and ring fingers. A positive Tinel's sign is usually present at the compression site, with wasting and weakness of the intrinsic muscles of the hand (Figure 36.40). Foment's sign will be positive due to weakness of the adductor pollicis (Figure 36.41). Nerve conduction studies have an unpredictable diagnostic value in the early stages. X-rays may confirm medial osteophytes.

Treatment

Splints preventing elbow flexion at night may be useful. If symptoms persist, surgery including simple nerve decompression (most cases), partial medial epicondylectomy, and/or anterior

Figure 36.31 (a and b) Linked total elbow replacement.

Figure 36.33 Osteochondritis dissecans of the capitellum (Panner's disease).

Figure 36.35 X-rays showing loose bodies in the elbow.

Figure 36.34 Synovial chondromatosis.

Figure 36.36 Loose bodies removed arthroscopically from patient in Figure 36.35.

transposition of the nerve can be performed. Transposition is necessary in cases of valgus deformity or if the nerve is unstable after decompression (Summary box 36.10).

Summary box 36.10

Other common elbow problems

- Loose bodies cause locking and can be removed arthroscopically
- If the ulnar nerve is compressed weakness and wasting will be seen in the hands
- Simple decompression is usually successful

TUMOURS OF THE UPPER LIMB

Tumours are discussed in Chapter 39.

Figure 36.37 Olecranon bursitis.

Figure 36.38 Large chronic olecranon bursa with dense calcific deposit.

Figure 36.39 Anatomy of the cubital tunnel site for ulnar nerve compression, with a view of arthroscopic ulnar nerve decompression (inset). FCU, flexor carpi ulnaris; MCL, medial collateral ligament.

Figure 36.40 Intrinsic muscle wasting due to ulnar neuropathy.

Figure 36.41 Foment's sign tests the adductor pollicis. Patient is asked to hold a piece of paper in a side pinch between the thumb and the index finger. The examiner attempts to pull the paper out. Due to weakness of the adductor pollicis the patient will compensate by flexing the flexor pollicis longus that is supplied by the anterior interosseous nerve.

HAND

The index finger works against the thumb for a fine pinch grip; the thumb can press against the side of the index finger for a key grip; the tip of the index and middle fingers provides a tripod pinch; all fingers curl for hook grip while the little and ring fingers provide the most power when making a fist. A stable wrist is required to allow good hand function.

Clinical history and physical examination

The occupation, sports and recreation (especially music) and hand dominance are all important information needed when treating a hand problem.

The examination of the hand should assess sensation, movement, power and coordination. A check should also be made for the rotational malalignment of the digits (Figure 36.42).

Figure 36.42 Rotational deformity of the little finger.

Investigations

Radiographs assess for arthritis or tumours. Electrophysiological studies may be required to assess nerve function. MRI is useful for diagnosing avascular necrosis and ligament injuries.

Hand swelling and stiffness

Swelling followed by stiffness is the arch enemy of hand rehabilitation. The hand will swell after injury, surgery or infection. In response the wrist flexes and then there is compensatory metacarpophalangeal joints' extension and interphalangeal flexion. If action is not taken this position will become permanent as collateral ligaments shrink and tissues fibrose. Hand elevation to reduce swelling, splintage in position of safety to prevent collateral shortening ('Edinburgh' position described by James – full extension of the proximal and distal inter-phalangeal joints, and flexion to 90° of the metacarpal-phalangeal joint) and early mobilisation prevent permanent stiffness (Summary box 36.11).

Summary box 36.11

General principles of treatment

Avoid swelling and stiffness by:

- Elevation – reduce swelling
- Splintage – avoid contractures
- Movement – pump away swelling and encourage suppleness

Thumb ulnar collateral ligament injury

Chronic thumb overuse leads to stretching of the ulnar collateral ligament and instability (gamekeeper's thumb). The ligament can also rupture acutely if the thumb is forcibly abducted (skier's thumb). If valgus stress causes significant opening of the joint on the ulnar side then the ligament needs to be repaired surgically as the torn end can become trapped behind the adductor aponeurosis (Figure 36.43).

Triangular fibrocartilage complex

The triangular fibrocartilage is a complex consisting of the ulnocarpal ligaments and a meniscus form. It is continuous with dorsal and volar wrist capsules and stabilises the distal radioulnar joint. It can undergo traumatic or degenerative tears, presenting with ulna-sided wrist pain and distal radioulnar instability. An MR arthrogram and wrist arthroscopy aid diagnosis (Figure 36.44). Peripheral tears of the triangular fibrocartilage complex (TFCC) can be repaired (open or arthroscopically) while central degenerative tears are arthroscopically debrided.

Infections

Paronychia

Nail bed infection is the most common hand infection (Figure 36.45). After initial inflammation, pus accumulates beside the nail. It is best treated with incision and drainage, partial nail removal and antibiotics.

Felon

A felon is an abscess between the specialised fingertip septae in the distal pulp. It causes intense fingertip pain. It may lead to

Figure 36.43 Magnetic resonance imaging shows rupture of the ulnar collateral ligament of the thumb (skier's thumb).

Figure 36.44 Magnetic resonance imaging arthrogram showing peripheral detachment of the triangular fibrocartilage complex (TFCC).

Figure 36.45 Acute paronychia.

terminal phalangeal osteomyelitis. Incision and drainage covered by intravenous antibiotics is recommended.

Flexor tendon sheath infection

Flexor tendon sheath infections present as a painful, swollen, flexed finger. There is extreme pain with passive extension, tenderness along the tendon sheath and symmetric swelling (Kanavel's signs). Treatment is by closed sheath irrigation by a catheter or open drainage and intravenous antibiotics. If infection is untreated, tendon adhesion and necrosis occur. Infection can spread proximally, damaging the whole hand (Summary box 36.12).

Summary box 36.12

Treatment of hand infections

- Elevate, splint and give intravenous antibiotics
- Surgical drainage should include tendon sheath irrigation
- Early mobilisation

Mycobacterial infections

Tuberculosis may involve the tenosynovium, joints or bone. The most dramatic form is the compound palmar ganglion, with synovial swelling, proximal and distal to the transverse carpal ligament. Diagnosis is made by taking a biopsy. Synovectomy should be performed and the patient treated with the appropriate antibiotics.

Deep fascial space infections

These infections occur in the palm but may be limited to a web space. The whole hand becomes swollen and tender, as pus collects on either side of the septum. Treatment is incision and drainage with thorough washout of the wound. It is important that all deep spaces are opened and incision on both dorsal and volar sides of the hand may be needed.

Arthritis

Rheumatoid arthritis

Rheumatoid arthritis presents with classic symptoms: morning stiffness, symmetrical arthritis, hand deformities and rheumatoid nodules. Diagnostic criteria include seropositive rheumatoid factor and radiographic changes (Table 36.1). The rheumatoid synovitis (pannus) destroys ligaments, tendons and joints, producing pain, deformity and loss of function. Typical rheumatoid deformities in the hand include boutonnière (Figure 36.46), swan neck (Figure 36.47) and ulnar drift of the metacarpophalangeal joints with radial drift of the wrist (Figure 36.48). Activities such as thumb pinch and the opening of jars stress the weakened ligaments and become impossible to perform. The treatment should be dictated by pain and disability, not deformity (Summary box 36.13).

Summary box 36.13

Manifestations in rheumatoid arthritis

- Fingers: swan neck, boutonnière
- Extensor tendon rupture
- Flexor tendon rupture
- Flexor synovitis
- Metacarpophalangeal joints: flexion, ulnar deviation, subluxation, dislocation
- Wrist: radial deviation, carpal supination, prominent ulna head, extensor tenosynovitis

Management

The primary indications for surgery are: (1) pain relief; (2) functional improvement; (3) prevent disease progression; and (4) cosmesis. Patients may require many surgical procedures and a helpful axiom is to start proximally and work distally alternating

Table 36.1 Radiographic differences between rheumatoid and osteoarthritis.

Rheumatoid arthritis	Osteoarthritis
Periarticular osteoporosis/subchondral erosions	Subchondral sclerosis and cysts
Periarticular soft-tissue swelling	Less pronounced swelling
Joint space narrowing	Joint space narrowing
Marginal erosions	Marginal osteophytes
Joint deformity/malalignment	Less pronounced deformities
Ankylosis	Less common ankylosis

Figure 36.46 Boutonnière deformity.

Figure 36.47 Swan neck deformity.

Figure 36.48 Rheumatoid hand showing ulnar drift at the metacarpophalangeal joints.

Boutonnière is French for 'button-hole'.

between motion sacrificing and sparing procedures. The various procedures which can be considered are:

- 1 Synovectomy: improves pain, increases function and prevents tendon rupture, trigger digits and nerve compression (Carpal tunnel syndrome).
- 2 Distal ulna excision: reduces pain, prevents extensor tendon rupture or protects repaired extensor tendons. Distal ulna excision leads to instability and so in the young patient ulna head arthroplasty is preferred.
- 3 Arthrodesis of the wrist, thumb and some of the smaller joints: gives good pain relief, and creates a stable axis against which other parts can function.
- 4 Metacarpophalangeal and interphalangeal joint replacement: provides pain relief and functional improvement. Total wrist arthroplasty will also provide good pain relief and motion (Figure 36.49).
- 5 Tendon reconstructions: some ruptured tendons cause significant morbidity (Figure 36.50), often treated either by a tendon transfer or a local joint fusion.

Osteoarthritis

Wrist

The radiocarpal joint can develop primary or secondary osteoarthritis (after intra-articular trauma and infection). If conservative measures have failed then operative management includes limited or total wrist arthrodesis and total wrist replacement.

Hand

Females are more commonly affected than males. The commonly affected joints are the distal interphalangeal (Heberden's nodes), proximal interphalangeal (Bouchard's nodes) and the thumb carpometacarpal joints (Figure 36.51). Symptoms rarely correlate with the appearance clinically or radiographically. Treatment includes splinting, therapy and steroid injections. Surgical options include arthrodesis for distal interphalangeal (DIP) and proximal interphalangeal (PIP) joints (Figure 36.52), joint replacement (PIP and metacarpophalangeal joints) and

Figure 36.49 Total wrist replacement.

Figure 36.50 Rupture of the extensor tendons to the little and ring fingers.

Figure 36.51 Hand deformities secondary to osteoarthritis.

excision arthroplasty (excision of trapezium for thumb carpometacarpal joint). Joint arthrodesis eliminates pain at the expense of motion, but function is often well preserved.

Other forms of arthritis in the hand

Psoriasis especially affects the DIP joints. It is asymmetrical and causes fusiform swelling of the digits and nail changes. Gout causes pain, joint redness, occasional tophi, and can be difficult to differentiate from septic arthritis. Serum urate and negative microscopic birefringence of joint aspirated sodium urate crystals are diagnostic.

Figure 36.52 X-rays of the distal interphalangeal and proximal interphalangeal joints treated with arthrodesis (a) and joint replacement (b).

Dupuytren's contracture

Dupuytren's contracture is an autosomal dominant condition, common in northern Europe, predominantly in men in the fifth to seventh decades of life. It is associated with smoking, trauma, epilepsy, AIDS, hypothyroidism and alcoholic cirrhosis. It also appears very frequently as a clinical case in British surgical exams! The characteristic features are palmar nodules, skin puckering, cords of the palm and digits, and flexion contractures of the digits (Figure 36.53). It is most common on the ulna side of the hand. Garrod's knuckle pads (thickened skin on dorsum of proximal interphalangeal joint) are another feature visible on examination (Figure 36.54). It can also produce cords in the penis which cause it to become curved (Peyronie's disease) and may also produce plantar thickening (Ledderhose's disease). Surgery is indicated when the patient cannot put their hand flat on the table due to deformity or when flexion contracture develops in the PIP joint. Great care should be taken during surgery to avoid damage to the digital nerves which may be trapped in the fibrous tissue. At the end of surgery, it may not be possible to obtain closure of the skin, and so healing may have to be by secondary intention.

In the late stage of the disease, a fixed contracture of the metacarpal phalangeal and proximal phalangeal joints may develop. In these cases, excision of the fibrous bands will produce no improvement in the condition, and if the contracted finger is preventing useful function of the hand, then an amputation may have to be considered (Summary box 36.14).

Tendon disorders

Trigger digit

Triggering occurs in the fingers or in the thumb as a result of a size mismatch between the flexor tendon and sheath (usually at A1 pulley) in which it runs.

Figure 36.53 Dupuytren's contracture.

Figure 36.54 Garrod's knuckle pads.

Summary box 36.14

Dupuytren's contracture

- Autosomal dominant inheritance (trait)
- Fibroblastic hyperplasia with resultant skin nodules, cords and deformities
- Surgical management is indicated if hand cannot be placed flat
- Fixed flexion deformities mean that amputation is the only surgical option

The patient complains of painful locking of the finger either in extension or in flexion or both. There is a palpable nodule in the tendon. Management is a steroid injection into the sheath, and if this fails then surgical tendon sheath (A1 pulley) release should be performed, taking care not to cut too much of the pulley and create bowstringing of the flexor tendon. Trigger digits can occur in infants and usually resolve spontaneously.

De Quervain's disease

De Quervain's disease is caused by tenosynovitis of the abductor pollicis longus and extensor pollicis brevis in the first dorsal

Baron Guillaume Dupuytren, 1777–1835, surgeon, Hôtel Dieu, Paris, France, described this condition in 1831.

Sir Archibald Edward Garrod, 1857–1936, Regius Professor of Medicine, the University of Oxford, Oxford, UK described this condition in 1893.

Francois de la Peyronie, 1678–1747, surgeon to King Louis XIV of France and founder of the Royal Academy of Surgery, Paris, France.

Georg Ledderhose, 1855–1925, a German surgeon, described this disease in 1894.

wrist compartment. It is predominantly seen in middle-aged females, and is associated with pregnancy (new mother's wrist), and inflammatory arthritis. The clinical features are radial wrist pain, tenderness, swelling (Figure 36.55) and a positive Finkelstein's test (pain with wrist and thumb in ulnar deviation while the thumb is fully flexed). The management options are non-steroidal anti-inflammatories, splintage, steroid injection and surgical release of the extensor retinaculum of the first dorsal compartment.

Compressive neuropathies

Median nerve (carpal tunnel syndrome)

The majority of cases of carpal tunnel syndrome are idiopathic. It is associated with diabetes, thyroid disorders, alcoholism, amyloidosis, inflammatory arthritis, pregnancy and obesity.

History

The patient presents with tingling and infrequently numbness in the radial three and a half fingers. Patients also complain of being woken at night with pain and that hanging their hand out of the bed provides relief. They may also complain of clumsiness when picking up small objects or carrying heavy ones.

On examination

Wasting of the thenar eminence is visible (Figure 36.56) and there is sometimes weakness of the abductor pollicis brevis. This is frequently bilateral. The tests for carpal tunnel compression are described in Chapter 33 but the most reliable are: (1) Tinel's – percussion over the carpal tunnel and (2) Phalen's test – reproduction of paraesthesia with full wrist flexion. Electrophysiological studies can confirm diagnosis with evidence of slowing of nerve conduction through the carpal tunnel. Non-operative treatment includes night splintage of the wrist in extension, and steroid injections. If surgery is required the median nerve is surgically decompressed by incising the roof of the tunnel (transverse carpal ligament) either open or through a small arthroscope (Summary box 36.15).

Summary box 36.15

Carpal tunnel syndrome

- Night pain is common and relieved by shaking the hand
- Thenar wasting is an advanced sign
- Tinel's and Phalen's tests are useful
- Treatment includes splints and surgical decompression

Ulnar nerve (Guyon's tunnel syndrome)

Ulnar nerve compression in Guyon's canal can lead to tingling and numbness in the ring and little fingers with hypthenar wasting. There is preservation of the dorsal sensations over the little and ring finger. Compression is due to a ganglion, ulnar artery aneurysm or a fracture of the hook of hamate.

Avascular necrosis of carpal bones

Idiopathic avascular necrosis of the lunate (Kienbock's disease) or scaphoid (Preiser's disease) can occur (Figure 36.57). The clinical presentation is of wrist pain and the diagnosis can be confirmed with x-rays and MRI. The natural history of the condition leads to collapse of the carpal bones and subsequent

Figure 36.55 De Quervain's disease.

Fritz de Quervain, 1868–1940, Professor of Surgery, Berne, Switzerland, described this form of tenosynovitis in 1895.

Jean Casimir Felix Guyon, 1831–1920, Professor of Genito-urinary Surgery, Paris, France.

Robert Kienbock, 1871–1953, Professor of Radiology, Vienna, Austria, described this condition in 1910.

arthritis of the carpus which may be best treated with a fusion of the wrist. This will at least give a strong and painless wrist. The limitation in movement produces a disability which is not as great as might be expected.

Ganglion cysts

Ganglion cysts are the most common cause of a swelling in the hand and are found most often on the dorsum (Figure 36.58), the volar (Figure 36.59) side of the wrist, over the dorsum of the DIP joint (myxoid cyst) or within the flexor tendon sheath at the base of the finger (seed ganglion). The dorsal and volar

wrist ganglions can cause discomfort. The swellings are smooth, fluctuant and transilluminable. Mucus cysts can frequently discharge and cause nail changes (Figure 36.60). Seed ganglions can be painful when gripping. Aspiration or surgical excision can be considered. Patients should be informed regarding possible recurrence.

Congenital malformations

There are many congenital malformations of the upper limb and these are discussed in Chapter 41.

Figure 36.58 (a) Clinical and (b) surgical appearance of dorsal wrist ganglion.

CHAPTER 37

Hip and knee

LEARNING OBJECTIVES

To understand:

- The anatomy and biomechanics of the hip and knee and its clinical implications
- The clinical presentation, aetiology and management of common hip and knee pathologies
- The principles of joint replacement including guidelines about deep vein thrombosis prevention
- The advances in surgical practice in this field

THE HIP JOINT

Applied anatomy

The hip is a ball and socket joint formed by the head of the femur and the cup-shaped acetabulum (Latin – little vinegar cup) (Figure 37.1). The joint allows a considerable range of movement in different planes but is still inherently stable because of both its bony anatomy and the static (ligaments) and dynamic (muscle) stabilisers. The static stabilisers are composed of the ligaments (iliofemoral and pubofemoral ligaments anteriorly and the ischiofemoral ligament posteriorly), the joint capsule and the labrum, whereas the muscles running across the

joint (short external rotator muscles posteriorly, the iliopsoas anteriorly and the hip abductors laterally) constitute the dynamic stabilisers. The acetabular labrum is a fibrocartilagenous structure which is triangular in cross section and attached to the rim of the acetabulum except at its base where it is replaced by the transverse ligament. It helps in deepening the socket thereby enhancing stability. It also acts as a fluid seal and thereby helps improve joint lubrication. The femoral head derives its blood supply mainly from the retinacular branches of the medial circumflex femoral artery and there is a small contribution from the artery of the ligamentum teres (Summary box 37.1).

Summary box 37.1

Anatomy

- The hip joint is a ball and socket joint, which is stabilised by static and dynamic stabilisers
- Static stabilisers include the capsule, ligaments and labrum
- Dynamic stabilisers consist of the muscles acting across the joint
- Blood supply to the femoral head is mainly derived from the medial circumflex femoral artery

Biomechanics of the hip joint

Kinetic analysis reveals that forces as high as eight times body weight can be exerted across the hip joint during activities of daily living and this is primarily the result of contraction of muscles crossing the joint. The abductors, because of their insertion on the greater trochanter, help in supporting the pelvis when the patient stands on one leg and thereby form the basis of a Trendelenburg test (Figure 37.2) (Summary box 37.2).

Friedrich Trendelenburg, 1844–1924, Professor of Surgery successively at Rostock (1875–1882), Bonn (1882–1895), Leipzig (1895–1911), Germany. The Trendelenburg position was first described in 1885.

Figure 37.1 Anatomy of the hip joint.

Summary box 37.2**Forces going through the hip joint**

- Lifting leg from bed – one and a half times body weight
- Standing on one leg – three times body weight
- Running and jumping – ten times body weight

Conditions affecting the hip joint

Common hip pathologies in the paediatric age group and secondary to trauma are covered in Chapters 41 and 29, respectively. This chapter focuses on the acquired pathological conditions in the adult.

Avascular necrosis

Avascular necrosis (AVN) or osteonecrosis of the femoral head occurs because of an interruption in the blood supply to the femoral head, which causes bone death. This leads to collapse of the femoral head causing secondary osteoarthritis subsequently. AVN can be primary (idiopathic) or secondary to other pathology (Table 37.1).

Table 37.1 Aetiology of avascular necrosis of the femoral head.

Sickle cell disease
Haemoglobinopathies
Caisson disease ('the bends' in divers)
Hyperlipidaemia
Systemic lupus erythematosus
Gaucher's disease
Chronic liver disease
Antiphospholipid antibody syndrome
Radiotherapy
Chemotherapy
Human immunodeficiency virus
Hypercoagulable states (protein C and protein S deficiency)
Steroids
Alcohol excess
Idiopathic (see Perthes' disease, Chapter 41)

Clinical features

Avascular necrosis usually affects men aged from 35 to 45 years and is bilateral in over 50 per cent of patients. The patient is frequently asymptomatic in the early stages. As the disease progresses the patient may complain of an ache in the groin, walk with a limp and clinical examination may reveal limitation of movement.

Investigations

A weight-bearing anteroposterior (AP) radiograph of the pelvis along with a lateral radiograph will show the classical features of AVN including increased sclerosis in the early stages, the crescent sign indicating subchondral bone resorption. In the late stages there may be flattening indicating a segmental head collapse (Figure 37.3). However, radiographs may be normal in the early stages of the disease and, therefore, the most sensitive

Figure 37.2 Load on the hip joint when subject (weighing W) stands on one leg. Hopping increases the load from 4 to 10 W .

and specific way of investigating these patients is with magnetic resonance imaging (MRI). MRI allows accurate assessment of the extent of involvement and can also identify associated bone marrow changes. This helps in early diagnosis and prediction of prognosis (Figure 37.4). In 1985, Ficat classified the disease into five stages. In 1995, Steinberg modified this classification into seven stages based upon the type of radiological change on MRI and radiography (Table 37.2). Stages I–IV are further divided into A, B or C depending upon the extent of involvement of the femoral head.

Treatment

Conservative treatment usually leads to poor results and is therefore not recommended. The choice of surgical treatment depends on whether the head has collapsed or not. In the pre-collapse group the principle is to preserve and preferably encourage revascularisation of the femoral head, whereas in the collapse group the aim is to bring the undamaged parts of the femoral head into the load bearing area. The surgical treatment for the pre-collapse stage includes core decompression, which is aimed at relieving intravascular congestion in the femoral head and thereby pain. This can be achieved with or without bone grafting; a vascularised bone graft can also be used to stimulate bone formation.

Once the femoral head has collapsed, either a femoral osteotomy (which aims to transfer the weight-bearing area of the

A **caisson** is a watertight chamber used to protect construction workers during the building of underwater structures. Caisson disease (also called decompression sickness or bends) occurs in construction workers when they leave the compressed atmosphere in the caisson and are rapidly brought up to enter normal atmospheric conditions.

Figure 37.3 (a and b) Radiological appearance of avascular necrosis of the femoral head.

femoral head and thereby protect the collapsed segment), or a joint replacement (if degenerative changes have set in) is the preferred option. The choice is resurfacing arthroplasty (Figure 37.5) or a total joint replacement (Figure 37.6) (Summary box 37.3).

Table 37.2 Steinberg's classification of avascular necrosis of the femoral head.

Stage	Description
0	Normal or non-diagnostic radiograph, bone scan or MRI
I	Normal radiograph, abnormal MRI or bone scan
II	Sclerosis and cysts
III	Subchondral collapse, crescent sign
IV	Flattening of the head, normal acetabulum
V	Acetabular involvement
VI	Obliteration of joint space

MRI, magnetic resonance imaging.

Figure 37.4 Magnetic resonance imaging scan of the hip joint showing avascular necrosis and the extent of involvement of the femoral head.

Summary box 37.3

Avascular necrosis of the femoral head

- Patients can be asymptomatic in the early stages and therefore a high index of suspicion is necessary for initial diagnosis
- Magnetic resonance scans are needed for early diagnosis
- Treatment is based upon whether the patient presents before or after the femoral head has collapsed
- In the pre-collapse stage treatment focuses on revascularisation
- In the collapsed stage the aim is to replace the damaged joint surface
- Prognosis is dependent upon the extent of head involvement

Osteoarthritis

Introduction and aetiology

Osteoarthritis (OA) is termed as primary when no predisposing cause can be found and traumatic is when it develops after an insult to the hip joint. A multitude of factors including genetic, biochemical and mechanical influences have been implicated in the development of primary OA. The exact mechanism for the development of primary OA remains unknown and it is therefore termed idiopathic. Recently, femoroacetabular impingement (FAI) has been proposed as an aetiological factor responsible for the development of primary OA. The causes of OA of the hip are given in Table 37.3.

Clinical features

Osteoarthritis of the hip affects 10–25 per cent of those over the age of 65 years. The most consistent symptoms are groin pain and limitation of movement. The pain may also radiate down to the knee joint, and in some cases the only presenting feature may be a painful knee. In the early stages of the disease, pain is activity-related but as the disease progresses the patient also complains of pain at rest. The patient frequently complains of

Figure 37.5 Anteroposterior (a) and lateral (b) radiographs of the hip showing a resurfacing arthroplasty.

Figure 37.6 Radiograph showing an uncemented total hip replacement *in situ*.

night pain and may also find it difficult to get into a comfortable position while sleeping. Functionally, most have difficulty in putting on their shoes/socks and getting into and out of a bath or a car. As the pain increases, the joint gradually loses its movement because of muscle spasm, capsular contracture and osteophyte formation.

Clinical examination may reveal gluteal muscle wasting. There may also be a limp with a positive Trendelenburg sign. Leg length discrepancy (usually shortening) and limitation of movement, particularly internal rotation, are consistent features. Many patients present with a fixed flexion deformity. This is best elicited by a modified Thomas' test (see Chapter 33).

Investigations

The characteristic features on x-ray are: (1) a reduction of joint space, (2) sclerosis in the periarticular bone, (3) subchondral cysts and (4) osteophyte formation (Figure 37.7). Eventually, a collapsed femoral head may also be evident.

Treatment

There is no specific pharmacological therapy for osteoarthritis;

Table 37.3 Aetiology of osteoarthritis.

Primary

Cause unknown, termed idiopathic
Femoroacetabular impingement implicated as a possible cause

Secondary

Trauma
Avascular necrosis
Inflammatory arthropathy (e.g. rheumatoid arthritis)
Perthes' disease
Developmental dysplasia of the hip
Slipped capital femoral epiphysis
Septic arthritis

however, conservative treatment with non-steroidal anti-inflammatories, regular exercise, physiotherapy and modification of lifestyle with loss of weight does help. Patients should also be encouraged to use walking aids (usually a walking stick in the opposite hand to offload the affected joint).

The indications for surgery are relentless pain, limitation of lifestyle and activities of daily living, and failure of conservative treatment. The surgical options include an arthrodesis (fusion), an osteotomy (realignment) or a joint replacement.

More and more joint replacements are now being performed. The indications are based on limitation of lifestyle and individual needs, thereby making it a truly life-improving operation (Summary box 37.4).

Inflammatory arthritis

The hip joint can also be affected by inflammatory arthritides; however, these are not as common as OA. This group includes rheumatoid arthritis, ankylosing spondylitis, gout and chondrocalcinosis, juvenile rheumatoid arthritis and systemic lupus erythematosus.

Figure 37.7 Anteroposterior (a) and enlarged anteroposterior (b) radiographs of the hip joint showing osteoarthritis.

Summary box 37.4

Osteoarthritis of the hip

- Osteoarthritis is a non-inflammatory condition leading to progressive damage of the articular cartilage
- The most consistent features are groin pain and limitation of movement
- Characteristic radiological findings include reduction of joint space, joint-line sclerosis, subchondral cysts and osteophyte formation
- Conservative treatment includes walking aids, non-steroidal analgesics and physiotherapy
- Surgical options include osteotomy, arthrodesis or a joint replacement

Surgical procedures

Osteotomies around the hip

The goal of an osteotomy around the hip is to redistribute forces evenly across the joint, thereby eliminating excessive point loading. This can be achieved by performing an osteotomy on

the femoral or the acetabular side, depending upon the desired goal, e.g. an excessive valgus neck–shaft angle and an uncovered femoral head on the lateral aspect can be corrected by carrying out a varus femoral osteotomy. Similarly, a redirection osteotomy on the acetabular side can also be performed to improve coverage of the femoral head. The common indications for an osteotomy around the hip include:

- developmental dysplasia of the hip;
- Perthes' disease;
- OA in a young patient;
- slipped upper femoral epiphysis;
- AVN.

Ideally, an osteotomy should be considered in a young patient who maintains a good range of movement of the hip and radiographs show a reasonable amount of joint space. Thorough preoperative planning is essential to assess whether the desired position can be achieved postoperatively. Three-dimensional computed tomography (CT) scans may be helpful for appropriate preoperative planning.

Arthrodesis of the hip

Arthrodesis or fusion of the hip is an uncommon operation. It is generally reserved for young patients with severe osteoarthritis who have heavy manual jobs and in whom joint replacements would fail fairly quickly. The aim is to achieve a painless joint by fusing it in a functional position, which is about 30° of flexion, 15° of external rotation and 5° of abduction. This can be achieved by an intra-articular dynamic hip screw or by an extra-articular plate with screws.

Several problems can occur following an arthrodesis, including altered gait and excessive loading of the ipsilateral knee, the contralateral hip and the spine. Degenerative change in these joints in the long term is the rule rather than the exception.

Joint replacement

Over 70 000 total hip replacements are performed annually in the UK. The results of surgery are encouraging. In good hands, up to 95 per cent of patients will have a well-functioning hip replacement at ten years after surgery. In the best series, 85 per cent will still be functioning at 20 years, although many are still in place only because the patients are too old and infirm for them to be revised. Following surgery, pain is reduced, mobility increases and sleep as well as social and sexual function is improved. Nevertheless, with the ever increasing number of patients with joint replacements, the number of patients whose replacement has failed or worn out and who now want a revision, or even a re-revision, is rising rapidly.

Principles and design of hip replacements

Any joint replacement should be biocompatible and made of inert materials. It should be well fixed to the host tissue and the design should incorporate features to allow a good range of movement and stability. The bearing surfaces should produce minimal friction (to prevent early loosening), and the material released from the bearing surface should be non-toxic. It should remove the minimum amount of the patient's bone, so that revision is possible, and it should create a biomechanically stable joint. Finally, any joint implanted should ideally outlive the patient and be cost effective (Summary box 37.5).

Summary box 37.5

Features of an ideal joint replacement

- Biocompatible
- Well fixed to the host tissue, stable and allowing a good range of movement
- Bearing surfaces should be designed to minimise friction
- Material released from the bearings should be non-toxic
- Remove the minimum amount of bone
- Produce mechanical stability
- Should ideally outlive the patient

Materials for the femoral component

Most of the implants available currently are made of cobalt–chrome alloy or stainless steel or titanium. Metal implants are able to withstand high loads, are relatively inert and can be manufactured easily. However, they do pose problems in terms of ion release if they are used as bearing surfaces. Also, corrosion can be a cause for concern if two dissimilar metals are used.

Bearing surfaces (the acetabular cup)

The total hip replacement (THR) designed by Charnley uses a joint surface of metal on high-density polyethylene. This is described as a hard-on-soft bearing surface and has a low coefficient of friction. High-density polyethylene has good shock-absorbing properties but does wear slowly over the years, producing small particles that can stimulate an inflammatory response in the joint, which then leads to aseptic loosening of the joint. The activated macrophages resorb bone and may also stimulate osteoclasts to do the same. There has, therefore, been a move towards using bearing surfaces with a lower wear rate, such as metal on metal or ceramic on ceramic. Although the wear rate of these newer bearing surfaces is less than conventional metal-on-polyethylene articulations, the wear particles are smaller (nano rather than micro) and there is increasing evidence that these implants are less forgiving than conventional metal on polyethylene THRs when surgical technique is suboptimal. Ceramic femoral heads bearing on polyethylene cups have far lower friction, but ceramic femoral heads on ceramic acetabular cups have the lowest friction of all. However, they are expensive to manufacture and produce small-sized wear particles. A summary of the advantages and disadvantages of each bearing surface is provided in Table 37.4.

Fixation of implants

Artificial joints must be secured into the bones each side of the joint so that the implant does not work loose. This can be achieved with the help of cement or biological interdigitation between the prosthesis and bone (Table 37.5).

Sir John Charnley, 1911–1982, Professor of Orthopaedic Surgery, University of Manchester, Manchester, UK. He pioneered the hip replacement operation. The first hip replacements he made were from a hard plastic (Bakelite). They all broke within a year but the patients were so happy during that year that he was encouraged to persevere with new designs including high density polyethylene. In 1962 he moved his practice to Wrightington Hospital, Appley Bridge, which became a place of pilgrimage for young orthopaedic surgeons from all over the world wishing to specialise in hip replacement. In the same hospital, The John Charnley Research Institute was opened by his wife in 1992. In September 2010, the Royal Mail issued a series of stamps commemorating medical breakthroughs. The 60 pence stamp featured John Charnley's hip replacement operation as an x-ray.

Table 37.4 Bearing surfaces.

Type of bearing	Advantages	Disadvantages
Metal on polyethylene	Proven efficacy; easy to manufacture; cheap	High friction; high wear rates; wear particles excite an inflammatory response, which leads to osteolysis
Ceramic on polyethylene	Lower friction	Expensive; ceramic fracture can be a problem
Ceramic on ceramic	Low friction	Very expensive; ceramic can fracture, squeaking
Metal on metal	Lowest friction	Bad reputation as has failed in the past; metal ion release is a problem; expensive

Table 37.5 Fixation of implants.

Method of fixation	Advantages	Disadvantages
Cemented	Implant does not need to fit cavity exactly; well-proven results	Cement gets hot; fragments may cause third-body wear and stimulate aseptic loosening; difficult to remove at revision; non-biological and static fixation
Uncemented	No cement needed; fixation more secure; dynamic and biological fixation	Fit must be perfect; osseous integration does not always work; expensive

Traditionally, hip replacements were fixed into a bed of polymethyl methacrylate (PMMA) cement (Figure 37.8a). The cement acts as a grout (spacer) and not as a glue between the implant and the bone. In the majority of cases, it gives an excellent outcome. As the cement sets during surgery, some of the monomer is released into the patient's bloodstream. This can cause a drop in blood pressure.

On the other hand, biological fixation can be achieved by providing a rough surface on the prosthesis or by coating the surface of the prosthesis with hydroxyapatite, an osteoconductive agent, to encourage bone to bond to the prosthesis (Figure 37.8b). These cementless devices are increasingly used although they can be associated with higher implant costs, increased risk of intraoperative fracture and difficulty in removing them if revision surgery is needed.

Surgical approaches to the hip, postoperative course and complications

The operation can be performed via a posterior approach, an anterolateral or Hardinge approach, a trochanteric osteotomy or an anterior approach (Table 37.6). Each approach has its own

advantages and disadvantages. There is also a move towards minimally invasive surgery and shortening the size of the incision. The proponents of this concept have described a two-incision approach wherein the femoral component is inserted via a small incision around the greater trochanter and the acetabular component via an incision in the groin. Although the concept is attractive, no long-term benefits have been conclusively shown in hip surgery over the conventional technique. Eventually, whichever approach is taken, it is essential to be able to implant a prosthesis that has the correct offset, a correct centre of rotation, the correct component orientation and which equalises leg lengths and carries a minimal risk.

Table 37.6 Surgical approaches to the hip.

Surgical approach	Anatomical interval and muscle
Posterior	Along the fibres of the gluteus maximus
Anterolateral/ Hardinge	Parts of the gluteus medius and minimus are reflected off the greater trochanter
Anterior	Interval is developed between the sartorius and rectus femoris and the tensor fascia lata
Trochanteric	A trochanteric osteotomy is required

The postoperative course involves a 3–7-day stay in hospital where the physiotherapist encourages the patient to mobilise safely and independently, avoiding any movements which might lead to a dislocation (Figure 37.9). Before discharge, the occupational therapist assesses the patient's home circumstances and arranges for any modifications that may be required to assist the patient, e.g. a raised toilet seat. Follow-up visits are arranged at 6 weeks and at one year post-surgery. Although hip replacement is a fairly successful and safe procedure, it does have associated complications. A comprehensive list of complications is given in Table 37.7.

Table 37.7 Complications of total hip replacement.

Intraoperative complications

Nerve injury – sciatic, femoral and obturator
Vascular injury – femoral vein and artery
Femoral fracture
Fragments of cement left in joint

Postoperative complications

Deep vein thrombosis and pulmonary embolism
Infection
Dislocation (Figure 37.9)
Leg length inequality
Heterotopic ossification
Implant loosening

Deep vein thrombosis (DVT) is relatively common if no precautions are taken to reduce this risk. Use of regional anaesthesia

Figure 37.8 Radiographs of a cemented (a) and non-cemented (b) femoral component.

and early postoperative mobilisation are invaluable in reducing this risk. In addition, either mechanical devices (thromboembolic deterrent (TED) stockings or foot pumps) or medication (low molecular weight heparin or warfarin or oral anticoagulants) are commonly prescribed for a period of 4–6 weeks after surgery to reduce the risk of DVT.

Revision total hip replacement

Revision of a total hip replacement is required if the patient is symptomatic secondary to failure of the implant by loosening (Figure 37.10), recurrent dislocations or a periprosthetic fracture. Loosening of the implant can occur because of an infection or as a result of aseptic osteolysis caused by an inflammatory response secondary to particle wear.

In the initial stages of loosening the patient complains of pain, which is experienced mainly on weight-bearing. A history of infection in the immediate postoperative period may suggest infection as a cause of premature implant loosening. The infection is likely to be low-grade with *Staphylococcus epidermidis* multiplying slowly within a glycocalyx coating, so normal measures of infection such as a raised C-reactive protein may be equivocal.

If the loosening is secondary to infection, a two-staged revision is usually preferred. The first stage consists of implant removal, a thorough debridement and implantation of an antibiotic-loaded cement spacer. Multiple deep specimens are sent for bacteriology to determine the organism and its sensitivity. The patient is put onto appropriate antibiotics for a period of 6 weeks or more. At the second stage of the procedure, the cement spacer is removed and a new prosthesis implanted. In the case of aseptic loosening, revision is performed as a single-stage procedure. If there has been a significant amount of bone loss, bone grafting may be required and the patient should be advised of this preoperatively. The results following a revision hip replacement are not as good as those following a primary total hip replacement, and the rate of complications, especially dislocation, is also higher (Summary box 37.6).

Summary box 37.6

Revision total hip replacement

- Needed when the primary total hip replacement fails
- Patients usually present with pain on weight bearing
- Aseptic loosening of one or both components is the most frequent indication for revision

Femoroacetabular impingement

Femoroacetabular impingement has increasingly been recognised as a cause of secondary hip OA. The non-spherical portion of the femoral head is assumed to exert abnormal shear and compressive forces on the corresponding portion of the acetabular cartilage on vigorous hip flexion with internal rotation. Patients typically present with groin pain and MRI arthrogram typically reveals acetabular rim lesions and aberrant femoral head morphology.

Two distinct types of FAI have been described – cam and pincer, although many patients have a mixed picture with both morphologies occurring simultaneously. Pincer impingement is a result of anterior overcoverage or retroversion of the acetabulum

while cam impingement is secondary to abnormal morphology of the femoral head/neck junction. Treatment options for FAI depend on patient symptoms and vary from conservative treatment to hip arthroscopy to address labral pathology and impingement to periacetabular osteotomy.

THE KNEE

Applied anatomy

The knee joint is a synovial hinge joint. It consists of two tibio-femoral joints (condyloid) and the patellofemoral joint (sellar or saddle shaped). Its shape makes the joint inherently unstable, but stability is achieved by a combination of static (ligaments) and dynamic stabilisers (muscles acting across the joint).

Interposed between the tibial and femoral condyles are the medial and lateral menisci. These fibrocartilaginous structures aid shock absorption, increase the area over which load is taken and have a role in AP stability (Figure 37.11). Medial meniscal tears are three times more common than those in the more mobile lateral meniscus. The outer third of the meniscus is vascular and so can be repaired allowing tears to heal.

The medial and lateral collateral ligaments are the primary restraints to valgus and varus stress, respectively. The medial collateral ligament is a broad, flat ligament and is composed of a superficial and a deep layer. The deep layer is attached to the medial meniscus. The lateral collateral ligament is a simple cord-like structure.

The cruciate ligaments are vital for AP stability. Each cruciate ligament comprises two bundles. The anterior cruciate ligament (ACL) is composed of an anteromedial bundle that is tight in flexion and a posterolateral bundle that is tight in extension. The posterior cruciate ligament (PCL) has an anterolateral bundle (tight in flexion) and a posteromedial portion (tight in extension). The ACL and PCL prevent anterior and posterior translation of the tibia on the femur, respectively.

The knee has bursae surrounding it which can become inflamed and infected (Summary box 37.7).

Figure 37.9 Dislocation of the hip.

Figure 37.10 Acetabular loosening.

Figure 37.11 Anatomy of the knee joint.

Summary box 37.7

Anatomy of the knee joint

- Complex synovial hinge joint
- The shape of the joint surfaces makes it inherently unstable
- The static stabilisers are the joint capsule, menisci, cruciate and collateral ligaments
- The dynamic stabilisers are the quadriceps and hamstring muscles

Biomechanics

Axes of the lower limb

The mechanical axis of the lower limb runs from the centre of the femoral head, through the intercondylar notch of the knee to the centre of the ankle joint. The angle between the anatomical and mechanical axes of the femur is called the valgus angle (usually 5–7°) (Figure 37.12).

Kinematics and kinetics

Knee motion is predominately in the sagittal plane. A limited degree of rotation also occurs and increases as knee flexion increases. The normal range of motion is between 5° of hyperextension and 135° of flexion. MRI of cadaveric knees has revealed that during knee flexion, a combination of rolling and sliding of the femur on the tibia.

The biomechanical role of the patella is to function as a pulley for the quadriceps. It increases the power of the quadriceps by increasing the lever arm. It has the thickest articular cartilage in the body and is designed to withstand loads as high as 20 times body weight when jumping (Summary box 37.8).

Figure 37.12 Axes of the lower limb. Anatomical and mechanical axes are coincident. Adapted from Miller, M. *Review of Orthopaedics*, 4th edn. 2004, Elsevier, Philadelphia. By kind permission of the publishers.

Summary box 37.8

Biomechanics of the knee joint

- An artificial knee joint must have the joint surface parallel with the ground, and with the load transmitted equally between the condyles
- Knee motion is mainly in the sagittal plane with minimal rotation
- The patella acts as a pulley, increasing the lever arm of the quadriceps
- Loads of up to 20 times body weight are transmitted across the patella when jumping

Conditions affecting the knee joint

Osteoarthritis

Osteoarthritis commonly affects the knee joint. Females are affected more often than their male counterparts and more than 3 per cent of women aged over 75 years are affected. OA can be either primary (idiopathic) or secondary.

Clinical features

Pain is the chief symptom, made worse with use. With patellofemoral involvement, pain is worse on stairs. As the disease progresses exercise tolerance diminishes, pain becomes constant (disturbing sleep) and patients will become increasingly reliant on walking aids, and may even become housebound in severe cases.

Clinical examination reveals a limp where they spend a short time on the painful limb and drop their centre of gravity (bob their head) as they try to minimise the weight that they are taking through this limb. In osteoarthritic patients the deformity is usually varus with bone loss on the medial side, while in rheumatoid patients valgus deformity is commonplace. An effusion is frequently present and movement is restricted, particularly extension. Crepitus can be both palpable and audible.

Investigations

The radiographic features are joint space narrowing, subchondral sclerosis, osteophytes and subchondral cysts (Figure 37.13).

Some centres are increasingly using MRI to judge both articular cartilage involvement and the integrity of the ACL with a view to guiding future surgical intervention.

Treatment

Non-operative methods are the first line of treatment. Patients should be encouraged to lose weight, undertake regular exercise to prevent joint stiffness and use anti-inflammatory medication. Walking aids (e.g. a stick) may be beneficial. Intra-articular steroid injections can provide long-term pain relief, but if repeated often may actually cause more rapid degeneration of the joint.

Surgical options include osteotomy, arthrodesis or knee replacement. These are all discussed in turn below (Summary box 37.9).

Summary box 37.9

Knee osteoarthritis

- More common in females
- Can be primary (idiopathic) or secondary (e.g. post-traumatic)
- Main symptom is pain made worse by use
- Examination reveals swelling, and reduced range of motion with or without deformity
- The four key radiographic features are: joint-space narrowing, subchondral sclerosis and cysts and osteophytes
- Treatment is non-operative initially. Knee replacement is reserved for end-stage disease

Surgical procedures in the knee

Knee arthroscopy

Knee arthroscopy can be used in the diagnosis and treatment of articular cartilage defects, meniscal and ligament injuries. Arthroscopic washout/debridement for end-stage OA is a controversial area with varying support among orthopaedic surgeons; however, half of patients report short-term symptomatic improvement.

There are a number of other indications for knee arthroscopy summarised in Table 37.8.

Figure 37.13 Osteoarthritis of the knee.

Table 37.8 Indications for knee arthroscopy.

Torn meniscus – for resection or repair
Anterior/posterior cruciate ligament reconstruction
Loose body removal
Cartilage regeneration techniques including microfracture
Septic arthritis – for washout
Inflammatory arthritis – synovectomy
Osteoarthritis – ‘staging’ the disease, resection of degenerate meniscus and washout
Diagnosis of unexplained knee pain
Tibial plateau fractures; allows intraoperative assessment of the articular surface

Osteotomy

Osteoarthritis can lead to varus or valgus deformity of the knee. This results in excessive stresses on the affected compartment leading to premature degenerative change in that compartment. Osteotomy aims to divide the bone, correct the deformity and alter the load-bearing mechanics of the joint.

The most commonly performed operation is a high tibial osteotomy (HTO) for a varus knee. Realignment is achieved with either an opening-wedge medial HTO or a closing-wedge lateral HTO. In valgus knees with relatively mild deformity (less than 12°) a varus-producing HTO on the medial side can be performed. A deformity of 12° or more requires distal femoral varus osteotomy.

The ideal patient for osteotomy is a young and active, well-motivated individual with disease limited to one compartment.

Knee arthrodesis

The most common indication for knee arthrodesis is a failed total knee replacement. Other indications include uncontrollable sepsis, neuropathic joint, post-traumatic arthritis in a young patient or disruption of the extensor mechanism. The ideal position of fusion is 7° of valgus and 15° of flexion. Arthrodesis is performed using either a custom-made intramedullary nail or an extramedullary technique such as an external fixator.

Knee replacement

There are three compartments within the knee: medial and lateral tibiofemoral and patellofemoral. Osteoarthritis may affect these individually or collectively. The medial compartment is most commonly affected producing a varus deformity. For single compartment disease a unicompartmental replacement may be used while in tricompartmental disease a total knee replacement (TKR) is indicated.

Knee replacement can be regarded as a resurfacing procedure in which the tibial and femoral articular surfaces are replaced with metal and the menisci by a tough polyethylene insert.

The main indication for knee replacement is pain, especially when combined with deformity and instability. Knee replacement should be reserved until a patient’s quality of life is significantly impaired.

Unicompartmental knee replacement

The natural history of osteoarthritis reveals that in 92 per cent of

cases the disease begins in the medial compartment alone. This was the basis for the development of the medial unicompartmental knee replacement (UKR) which is available in either fixed or mobile bearing forms (Figure 37.14). A number of series report ten-year survival figures of over 90 per cent for UKR.

Prerequisites to undertake medial UKR include intact ligaments (especially ACL), disease limited to one compartment and varus/flexion deformities not more than 15°. The operation is now performed using minimally invasive techniques through a quadriceps-sparing incision. Advantages over TKR include more rapid recovery, shorter hospital stay and preservation of knee kinematics. It is a bone preserving procedure which, if it fails, allows straightforward conversion to TKR.

Lateral UKR is performed for lateral compartment disease; numbers are far less than medial UKR partly owing to a reported dislocation rate of 10 per cent.

Patellofemoral replacement is also performed, but again numbers are low in view of the scarcity of patients with isolated patellofemoral disease, and the unproven nature of the procedure.

Total knee replacement

Natural knee motion is complex. It involves translation and rotation about each of the x, y and z axes (six degrees of fre-

edom). It has proved very difficult to reproduce this natural motion in TKRs (Figure 37.15). In comparison to total hip replacement, patients with TKR find it hard to forget they have a knee replacement. Consequently, patient satisfaction is lower with TKR.

There are three types of TKR currently used: unconstrained, constrained-non-hinged and constrained-hinged. Almost all primary TKRs are unconstrained while the constrained types are used in revision total knee replacement when there may be significant bone loss and ligament deficiency.

The more constrained the implant the greater the force transmitted to the implant–cement–bone interface therefore increasing the risk of loosening.

The main aim of TKR is to create a mechanical axis (weight-bearing line) which passes through the centre of the femoral head, knee and ankle. The joint line should then be perpendicular to the mechanical axis. It should also be parallel with the ground. If the correct size of implants are used and exactly the right amount of bone is cut away from both the tibia and the femur, then the new joint surface will be placed exactly where the patient's original surface had been before disease supervened. The collateral ligaments will then provide stability without constraint and ensure the patella will track correctly on the femur (Summary box 37.10).

Figure 37.14 Unicompartmental knee replacement.

Figure 37.15 Total knee replacement.

Summary box 37.10

Aims of total knee replacement

- Mechanical axis through centre of knee
- Joint line perpendicular to mechanical axis
- Balance collateral ligaments
- Ensure patellofemoral joint tracks normally

Postoperatively, patients require intensive physiotherapy to regain quadriceps strength and to achieve full extension. In addition, they need at least 90° knee flexion to enable them to sit comfortably. The average length of hospital stay is between 5 and 7 days.

Complications

Complications following TKR can be broadly classified into intraoperative and postoperative (Table 37.9).

Table 37.9 Complications of total knee replacement.

Intraoperative

Malplacement of implants leading to instability or stiffness, or pain

Nerve or vessel injury including tourniquet damage

Fracture

Patellar tendon avulsion

Malalignment

Fat embolism

Postoperative

Infection

Deep vein thrombosis/pulmonary embolism

Pain/stiffness

Instability

Osteolysis

Component loosening

Dislocation

Revision total knee replacement

Implant loosening secondary to either infection or polyethylene-induced osteolysis are the main reasons for performing revision TKR. Other indications include periprosthetic fracture, malalignment (Figure 37.16), instability and patella maltracking. Regardless of the indication, as with any type of revision procedure it is important to exclude infection because this often warrants a two-stage rather than single-stage procedure. Although more technically challenging, the aims of revision TKR are no different to primary TKR, that is to provide a well-aligned, stable and pain-free knee. The revision burden of hips and knees is increasing with time and more complex revisions need to be performed as the patients are living longer, along with the primary joint replacement being offered at a younger age and in a more active patient.

Anterior cruciate ligament injury

The ACL is the most commonly injured ligament in the knee. It most commonly results from pivoting injuries in high energy contact sport (see Chapter 34) and may be associated with an audible ‘pop’ and immediate swelling, with the patient being ‘carried off’. The injury rate is higher among females than males.

Some controversy exists concerning the incidence of secondary OA in ACL-deficient versus reconstructed knees. However, chronic ACL deficiency is clearly linked with an increased incidence of complex meniscal tears and chondral injury.

Investigation

MRI of the knee is useful for confirming the ACL injury but also for excluding the involvement of other structures, including menisci, PCL and collateral ligaments, chondral surfaces and posterolateral corner.

Treatment

Some patients may decide that they have adequate stability in the knee once they have been through a full rehabilitation programme. Surgical reconstruction of the ACL should only be undertaken in those patients who have a full range of knee motion and good hamstring/quadriceps function preoperatively as otherwise results are poor.

Figure 37.16 Radiographs of a malaligned knee (a) and a well-aligned revised knee (b and c).

An isolated ACL injury is most commonly treated with an arthroscopic intra-articular reconstruction. Graft can be bone–patella, tendon–bone or four-strand hamstring autograft. Postoperative rehabilitation programmes are crucial to a favourable outcome.

Complications following ACL surgery are usually a result of incorrect tunnel placement (femoral tunnel too anterior limits knee flexion) and early surgery. Graft re-rupture rate is approximately 1 per cent per year.

CHAPTER 38

Foot and ankle

LEARNING OBJECTIVES

To understand:

- The basic anatomy and biomechanics of the foot and ankle
- The common problems affecting the foot and ankle in each age group
- The principles behind the treatment of each condition, be it conservative or surgical
- The significance of progressive neurological diseases

ANATOMY

There are 25/26 main bones in the foot (seven tarsal bones, five metatarsals and 13/14 phalanges) plus the two sesamoids of the hallux and a variable number of other sesamoid and accessory bones.

Movements at the ankle joint are mainly dorsiflexion and plantarflexion but, because the talus is wider anteriorly than posteriorly, dorsiflexion of the ankle leads to external rotation of the fibula at the syndesmosis. This means that the foot externally rotates with dorsiflexion and internally rotates with plantarflexion.

Stability is conferred upon the ankle by the shape of the medial, lateral and posterior malleoli and the integrity of the medial and lateral ligaments and the inferior tibiofibular ligaments.

The subtalar joint is divided into anterior, middle and posterior facets and, along with the talonavicular and calcaneocuboid joints, makes up the triple joint complex. These joints are responsible for inversion and eversion of the hind and midfoot. Most of this movement occurs at the talonavicular joint.

The second tarsometatarsal joint is recessed relative to the first and third and acts as a 'keystone'. Disruption of this joint (Lisfranc's injury) leads to loss of the transverse arch and an acquired flat foot.

The lower leg is divided into four compartments:

- 1 the superficial posterior – gastrocnemius, soleus and plantaris;
- 2 the deep posterior – tibialis posterior, flexor digitorum longus and flexor hallucis longus;
- 3 the lateral – peroneus brevis and peroneus longus;
- 4 the anterior – tibialis anterior, extensor hallucis longus, extensor digitorum longus and peroneus tertius.

There is only one muscle on the dorsum of the foot, the extensor digitorum brevis. The muscles on the plantar aspect of the foot are divided into four layers, the first being the most superficial. The plantar fascia is a very important structure that takes its origin from the heel and inserts into the bases of the proximal

phalanges of the toes. At toe-off, the fascia tightens and accentuates the medial plantar arch and helps provide a rigid lever arm, the so-called 'windlass mechanism'.

The blood supply of the foot is from the anterior tibial, the posterior tibial and the peroneal arteries. The following nerves supply sensation to the foot: posterior tibial, saphenous, sural, superficial and deep peroneal (Figure 38.1) (Summary box 38.1).

Summary box 38.1

Anatomy of the foot

- There are 26 major bones in the foot
- There are four layers of muscles in the sole of the foot
- The blood supply of the foot is from the anterior and posterior tibial arteries plus the peroneal artery

BIOMECHANICS

The walking cycle is divided into the stance (60 per cent) and swing (40 per cent) phases. The stance phase is divided into three intervals: (1) heel strike to foot flat; (2) foot flat until the body passes over the ankle; and (3) ankle joint plantarflexion to toe-off. During walking up to 12 per cent of the gait cycle is spent with both feet in the stance phase but with running there is a period when neither foot is in contact with the ground, the 'float' phase. During running the cycle time is shortened but the forces generated are very much increased (Summary box 38.2).

Examination

The examination of the foot is described in Chapter 33. The patient should be watched walking and both the foot and the footwear of the patient need examining when looking for abnormal load and wear.

Figure 38.1 Cutaneous nerve supply of the foot. Courtesy of Bartleby.com.

Summary box 38.2

Biomechanics

- The gait cycle is divided into swing and stance phases
- Running generates increased forces, shortens the gait cycle and has a float phase when neither foot touches the ground

PAEDIATRIC CONDITIONS

These are discussed in Chapter 41.

PATHOLOGY IN THE ADULT

The forefoot

Hallux valgus

Hallux valgus is deviation of the big toe away from the mid-line, i.e. towards the lesser toes, and is usually associated with a bunion, a swelling made up of both bone and bursa on the medial aspect of the first metatarsal head (Figure 38.2). It is a common condition that affects women more than men, and which is often bilateral. It is believed that the tendency to hallux valgus is inherited and that fully enclosed shoes accelerate the development of the condition.

With increasing deformity the first ray becomes defunctioned, and overload of the second metatarsophalangeal (MTP) joint results in pain and swelling with a prominent callosity beneath the second MTP joint and eventually hammering of the second toe.

The non-operative treatment of hallux valgus is unlikely to be acceptable to the younger patient as it involves relieving the load on the toe by use of an ugly shoe with a wide toe box. However, although hallux valgus may be merely a cosmetic

Figure 38.2 Hallux valgus and bunion.

problem, the fact that it is likely to progress makes surgical intervention reasonable provided that the patient realises that recovery can take from 6 to 12 months and that the surgery is not without risk.

For mild deformities a distal osteotomy (e.g. chevron) is usually adequate. For moderate deformities the surgeon is more likely to use a shaft (e.g. Scarf/Ludloff, Figure 38.3) or a basal (proximal chevron or crescentic) osteotomy. Severe deformities can be corrected by shaft and basal osteotomies but sometimes a fusion of the first tarsometatarsal joint (modified Lapidus) or a first MTP joint fusion can be effective. Basal osteotomies/fusions have a higher risk of abnormal elevation/depression of the rays resulting in overload of the rest of the forefoot. However, they do allow a massive correction. They are best stabilised using plates.

Operations such as a Keller's excision arthroplasty, where the proximal third of the proximal phalanx is excised, serve to defunction the toe and sesamoids and are reserved for low-demand high-risk patients where there is a high risk that healing of an osteotomy might fail.

The complications of surgery are infection, cutaneous nerve damage, recurrence/overcorrection of deformity, stiffness and overload of the second MTP joint (transfer lesion), and

Figure 38.3 Pre- (a) and postoperative (b) radiographs of a Scarf osteotomy.

10 per cent of patients have reservations about their outcome. Occasionally, patients develop early arthritis following surgery and require revision to fusion (Summary box 38.3).

Hallux rigidus

Hallux rigidus is a painful condition of the hallux MTP joint characterised by loss of motion especially in dorsiflexion and osteophyte formation on the dorsum and sides of the joint (Figure 38.4).

In adults there is often a history of trauma or repetitive microtrauma (sport) but, occasionally, there is a strong family history of the condition. Gout and rheumatological conditions may present in this way. Patients complain of stiffness and pain on weight-bearing.

The most effective non-operative treatment is provision of a stiff-soled shoe with a deep toe box or a rocker-soled shoe which are now available in high-street shops.

The mainstays of surgical management are injection/manipulation, cheilectomy (a radical debridement and excision of the part of the joint blocking movement) fusion and interposition arthroplasty (Keller's-type procedure).

Fusion is for the severely affected and is an effective means of

Figure 38.4 Clinical (a) and radiographic (b) appearances of hallux rigidus.

Summary box 38.3

Hallux valgus

- Bunions affect women more than men
- Patients with hallux valgus have inherited a tendency to develop the condition
- Not all patients need surgery
- The choice of operation is determined by the severity of the deformity and presence or otherwise of any arthritis

abolishing pain. A fusion will still usually allow sports participation (Summary box 38.4).

Sesamoid problems

Management includes offloading with orthotics and injections of steroids.

Lesser toe deformities

Non-operative treatment involves appropriate padding and footwear modification. For symptomatic flexible deformities soft-tissue surgery, such as flexor/extensor tenotomies \pm capsulotomy

Summary box 38.4**Hallux rigidus**

- Hallux rigidus can affect adolescents as well as adults
- Stiff-soled shoes with a deep toe box are the most comfortable type of shoe
- Cheilectomy and fusion are the mainstays of surgical treatment

is usually adequate but for fixed deformities bony procedures are required, such as interposition arthroplasty, fusion or excision arthroplasty.

Freiberg's disease

Freiberg's disease is an ischaemic necrosis of the epiphysis, resulting in pain and swelling of the joint (Figure 38.5). It will often settle with rest. Excision of the whole head should never be performed.

Morton's neuroma and metatarsalgia

Metatarsalgia usually occurs secondary to joint problems or irritation of a nerve. Morton's neuroma is a painful condition which in most cases arises from compression of the common digital nerve between the third and fourth metatarsal heads.

Diagnosis is confirmed by ultrasound. Non-operative treatments include advice about footwear, an orthosis (pre-metatarsal dome) to splay the metatarsal heads or an injection of steroids for short-term relief.

Surgery involves resection (the affected toes will be permanently partly numb if the nerve is removed) (Summary box 38.5).

Summary box 38.5**Morton's neuroma**

- Morton's neuroma most commonly affects the third web space
- Surgical excision of a neuroma is often successful but guided injections form the mainstay of treatment for most

Figure 38.5 Freiberg's disease.

Midfoot and hindfoot

The hindfoot comprises the talus and calcaneum. The midfoot comprises the remaining tarsal bones as far as the tarsometatarsal joints.

Arthritis

In the majority of cases pain will be the reason for the patient seeking help. On examination there is usually joint-line tenderness.

If a foot is swollen and deformed but relatively painless, there is likely to be an underlying neuropathy and urgent investigation and protection is required (Charcot foot).

Non-operative treatments include offloading painful areas, physiotherapy and intra-articular steroids. Surgery is reserved for those patients who fail non-operative treatment and involves fusion of the affected joints.

Ankle arthritis

The definitive operative treatment for arthritis of the ankle will usually be in the form of arthrodesis (fusion); this is often carried out via an open approach but arthroscopic ankle and triple arthrodesis are now established procedures and have better outcomes, more rapid recovery and fewer complications. Such techniques are mandatory in the presence of poor soft-tissue envelope or in the presence of a clotting diathesis. Ankle replacements are now available but the results are not as reliable.

The advantage of fusion is it has a known track record, good outcomes (90 per cent plus do well) and minimal morbidity, especially with modern arthroscopic techniques, but not all do well with fusion. Function following isolated fusion is virtually normal for most patients and this is probably due to increased mobility at other joints. However, this may precipitate arthralgia elsewhere.

Hindfoot (excluding ankle) arthritis

The triple complex refers to the subtalar (talocalcaneal), calcaneocuboid and talonavicular joints. These joints are often affected by arthritis. Treatment options are limited and if simple measures have failed, a fusion should be performed. Smokers and diabetics have a massively increased non-union rate for all foot fusion procedures and should be warned of this when they give consent.

Ankle with other hindfoot arthritis

If surgical input is required then one option is to do one set of joints and then see how the patient fares. Secondary surgery to the other joints can then be performed only if required. The alternative is to treat all joints at once. Modern techniques now use third-generation hindfoot fusion nails which fuse both ankle and subtalar joints and are inserted with an open or arthroscopic fusion technique.

A pantalar fusion is quite disabling but may be necessary in rheumatological patients with deformities/stress fractures, failed arthroplasty with subtalar joint involvement or avascular necrosis (AVN) collapse of talus.

Midfoot arthritis

The aetiology is usually not known but the risk factors include microtrauma, rheumatological causes, flat foot, Lisfranc or similar injuries (which may have been missed), Charcot and cavus

foot. Patients are best managed non-operatively with orthotics, shoes, analgesia and modifications of their lifestyle.

Inflammatory joint conditions

It is important to remember that knee deformity must be addressed before corrective hindfoot surgery is undertaken.

Rheumatological presentations in the foot

The early presentations of rheumatological disease may be with synovitis of the lesser MTP joints and widespread small joint disease, often in association with enthesopathy such as plantar fasciitis or Achilles tendonosis. However, the classic deformity is of hallux valgus with or without hallux rigidus deformity and subluxation or even dislocation of the lesser MTP joints.

The patient may present with a bunion and prominent lesser metatarsal heads which can often be felt to be dislocated on clinical examination, and are painful to palpation.

Excision of the metatarsal heads produces an almost instantaneous and gratifying relief of pain. If a plantar approach is used an ellipse of skin can be excised to move the metatarsal padding back over the end of the metatarsal. While most surgeons avoid scars on the plantar aspect of the foot wherever possible, this is one procedure when the results are good.

Midfoot

Rheumatological disease may also affect the midfoot and here the outcome is usually just pain and stiffness. Options are limited to injections and fusion surgery if non-operative measures have failed.

Hindfoot and ankle

Rheumatological disease also affects the hindfoot and ankle. Many patients require surgical hindfoot fusions.

The options for the ankle are discussed in the arthritis section. The rheumatological diseases also affect soft tissues. Patients are more prone to developing enthesopathy, tendinitis and tendonosis and even tendon rupture.

The Achilles tendon should never be injected with steroid for fear of rupture and similarly the tibialis anterior and tibialis posterior tendons are risky for injection (Summary box 38.6).

Summary box 38.6

Midfoot and hindfoot

- Joint disorders are degenerative or inflammatory
- The mainstay of surgical treatment remains fusion although ankle replacements are becoming more successful
- Rheumatoid arthritis must be medically controlled as well as possible before surgery
- Knee deformities should be corrected before tackling foot problems

Tendon disorders

Tenosynovitis occurs as a result of injury or overuse or is secondary to inflammatory joint conditions. Rest, anti-inflammatory medication and physiotherapy are often helpful but, in inflammatory conditions, tenosynovectomy may be required.

The tendons most commonly affected by degeneration are

the Achilles (Figure 38.6), tibialis posterior and peroneii (brevis more than longus).

Ruptured Achilles tendon

The Achilles tendon rupture is more frequent in the 40–50-year-old age group who are undertaking vigorous sport after a long period away from such activities. Many patients do not suffer the acute rupture classically described in all textbooks and many seem to have a series of micro tears that gradually lead to total rupture. Studies have shown that elderly patients with Achilles rupture regained 70–90 per cent of normal power with no treatment whatsoever when reviewed at one year and, for many patients, this is enough to allow them to return to normal function.

Non-operative options include a sprung ankle–foot orthotic (AFO) ankle brace.

Peroneal tendon problems

The peroneal tendons may develop a tendinosis, may sublux or may become involved in an inflammatory process with or without bony overgrowth at the inferior retinaculum (Figure 38.7). An associated varus heel will amplify the problem and will need addressing with an appropriate reconstruction/osteotomy or fusion.

Peroneal tendon subluxation can occur spontaneously or after injury. It may be associated with the groove at the back of the fibula being too shallow to contain the peroneal tendons, but may just be secondary to a superior retinaculum tear. The patient may be able to demonstrate a tendon subluxation over the fibula. Surgical repair is usually required and involves deepening of the groove.

Ankle instability

Most people who sustain an ankle sprain will recover, particularly if they receive prompt physiotherapy. However, some individuals develop significant instability. On examination an unstable ankle due to ligament disruption will show a marked 'anterior draw' sign.

If physiotherapy is unsuccessful at resolving the problem, a reconstruction may be needed with ligament augmentation.

Figure 38.6 Insertional Achilles tendinitis.

Figure 38.7 Split and degenerate peroneus brevis.

Osteochondral lesion of the talus

Patients with persistent pain in the ankle following an injury should be suspected of having an osteochondral lesion. Juveniles seem to have a high spontaneous recovery rate and surgery should not be necessary.

Synovitis

Many patients have ongoing pain following the ankle injury that is simply due to synovitis within the ankle joint. This may be treated non-operatively with an injection of steroid or may require surgical debridement.

Pes cavus

The development of unilateral pes cavus is likely to be arising from an upper motor neurone lesion so an appropriate neurological examination should be performed.

Pes cavus is usually bilateral and most cases will be associated with an underlying neurological condition, the most common being Charcot–Marie–Tooth disease. These patients may present with characteristic progressive small muscle wasting, thin calf musculature, hand symptoms, aches and pains, and cavovarus feet. Examination may show early loss of vibration sense. Precise diagnosis is confirmed with nerve conduction studies.

The key deforming force is always relative preservation of the tib post tendon. Surgical correction of deformity is often required. The principal goal of treatment is to obtain a foot which can be placed flat on the ground, and with the power of the muscles around the ankle in balance. It will be necessary to transfer or release the tib post tendon. The most commonly performed procedure is to transfer the tib post to the dorsolateral side of the foot, followed by lateralising of the heel with an osteotomy (Summary box 38.7).

Summary box 38.7

Pes cavus

- Pes cavus needs neurological investigation
- About 80 per cent of cases of pes cavus are associated with a neurological disease
- The most common cause is Charcot–Marie–Tooth disease
- Unilateral pes cavus – think diastematomyelia/tumour

Acquired flat foot

There is a wide range of normal appearances of adult feet. Pathological causes of a flat foot include:

- tibialis posterior tendon dysfunction;
- tarsometatarsal arthritis/injury (Figure 38.8);
- Charcot neuroarthropathy, e.g. diabetes;
- inflammatory/degenerative arthritis of the subtalar/talonavicular/naviculo-cuneiform joints;
- spring ligament rupture;
- tarsal coalition.

Figure 38.8 Tarsometatarsal arthritis.

Acquired adult flat foot

The tibialis posterior tendon tends to fail in overweight individuals and those who have flat feet. Often, after unaccustomed exercise, the tendon swells and is painful. The diagnosis is rarely made early. The condition occurs mainly in women and the key test is that the patient cannot stand on tiptoe on that leg alone. Many individuals will require surgical treatment in the form of a medial displacement calcaneal osteotomy, flexor digitorum longus or flexor hallucis longus tendon transfer and spring ligament repair. Failure to treat this condition can lead to spectacular deformity (Figure 38.9). An acute traumatic flat foot may develop in young athletes and military recruits after traumatic injury; here the injury is an isolated spring ligament tear and early surgery is needed to effect a repair (Summary box 38.8).

Summary box 38.8

Acquired flat foot

- Tibialis posterior tendon dysfunction and tarsometatarsal OA are common causes of an acquired flat foot
- Orthoses, rest and non-steroidal anti-inflammatory drugs (NSAIDs) can help with symptomatic relief
- Surgery is a major undertaking but often highly successful at achieving symptomatic relief

Figure 38.9 A tibialis posterior tendon-deficient foot.

Tumours

The three most common benign tumours of the foot are ganglia, giant cell tumour and angioleiomyomas (Figure 38.10); these tumours may need surgical excision.

The most common 'tumour' seen in the foot is the plantar fibroma or 'lederhosen disease', which presents as a painful often growing lump in the sole along the plantar fascia. The condition is linked to Dupuytren's and Peyronie's disease. Surgery is not helpful.

Infection

Septic arthritis in the foot or ankle is rare; when it occurs it usually follows a surgical procedure but it can also arise as a result of haematogenous spread. Treatment is immediate surgical drainage and administration of appropriate high-dosage antibiotics once cultures are obtained. The most common causative organism is *Staphylococcus aureus* with methicillin-resistant *S. aureus* (MRSA) becoming more common. Even with prompt treatment chondrolysis often occurs and subsequent degenerative changes develop rapidly.

In immunocompromised patients opportunistic infections can arise and, in diabetics, failure to treat with debridement can lead to amputation. It is important to realise that x-rays in the early stages of infection are usually normal and that diagnosis is made on clinical suspicion and with blood tests and more sophisticated imaging such as magnetic resonance imaging (MRI) or bone scanning.

Tuberculosis can affect the foot and is associated with major bony damage; it responds surprisingly well to debridement and appropriate anti-tuberculous therapy (Figure 38.11).

Diabetes

Diabetics have foot problems secondary to neuropathy and microvascular changes. They are at increased risk of infection and ulceration, and trauma (sometimes trivial) can lead to collapse of the foot, also known as Charcot neuroarthropathy (Figure 38.12).

Figure 38.10 Angioleiomyoma of the hallux.

Ulceration can lead to major morbidity and amputation (Figure 38.13). Ulcers need to be treated and, when ulcer healing has occurred, the aim should be to keep the foot ulcer free.

Charcot

Charcot is a disease whereby patients develop a neuropathic destruction of the joints. It is often described as painless but actually the majority of patients have some pain. In the Western world, diabetes is the biggest cause but in the rest of the world leprosy is also important. However, any other neurological condition can cause this condition.

Charcot disease often presents with a hot swollen, red extremity and is often misdiagnosed as cellulitis, gout, fracture or deep vein thrombosis (DVT), and a great many present late because of the difficulty in diagnosis. If there is no history of skin damage, infection is unlikely, but MRI and even biopsy can help differentiate between infection and Charcot. There are three stages to the process of Charcot neuroarthropathy, which takes up to 18

Figure 38.11 Tuberculosis of the foot.

Figure 38.12 Charcot foot. Radiographs taken at the time of a trivial injury (a) and 6 weeks later (b).

months to run its course: stage I, fragmentation; stage II, coalescence; and stage III, bone consolidation. The principle of treatment throughout is to maintain a foot-shaped foot to prevent late pressure ulcers. The acute Charcot foot requires appropriate splintage in a Charcot retaining orthotic walker (CROW) or a total contact cast (TCC), but many surgeons offer an aggressive early surgical approach. Surgical options include early stabilisation to prevent deformity or late reconstruction or removal of bony prominences to prevent ulceration (Summary box 38.9).

Summary box 38.9

Diabetes

Diabetics are prone to infection because of:

- Peripheral neuropathy
- Peripheral vascular disease
- Impaired resistance to infection

Figure 38.13 Diabetic foot ulcer.

Entrapment neuropathies

Any nerve supplying the foot can become entrapped and result in pain, and treatment often requires surgical decompression. Tarsal tunnel syndrome is much rarer than carpal tunnel syndrome in the hand.

Heel pain

The most common cause of heel pain is plantar fasciitis. Pain is located inferomedially within the heel and is worst first thing in the morning and after periods of rest. The majority of cases settle within 18 months and surgery is rarely required or successful.

LEARNING OBJECTIVES

- List the symptoms and signs which suggest the presence of a benign or malignant musculoskeletal tumour
- Recognise that a suspicious lesion should be referred to a centre of excellence for staging, biopsy and multidisciplinary assessment
- Understand why staging should be completed before biopsy
- Explain why a diagnosis is required before treatment
- Understand the principles of taking a biopsy
- Describe the principles of surgical treatment of musculoskeletal tumours
- List the aims of surgical treatment in metastatic disease
- How to manage a pathological fracture or impending fracture
- Recognise when a lesion is at risk of pathological fracture

The most common malignant bone tumours are metastases (Figure 39.1). Due to advances in oncological treatment, the number of patients presenting with skeletal failure due to metastatic disease is increasing. The most common tumours that metastasise to bone are breast, prostate, lung, kidney and thyroid carcinomas (Figure 39.2).

Multiple myeloma (Figure 39.3) is a malignant neoplasm

arising from the plasma cells in the bone marrow. It is usually multicentric. If the condition is solitary it is called plasmacytoma.

Malignant primary sarcomas of bone are very rare. The most common of these is osteosarcoma (Figure 39.4). Osteosarcoma has two incidence peaks, one in adolescence, the other later in life, arising in patients with Paget's disease and those who have

Figure 39.1 (a) Pathological fracture of the proximal femur through metastatic breast carcinoma. (b) X-rays of the whole femur show a further, more distal metastatic deposit.

Figure 39.2 Malignant tumours commonly metastasising to bone.

Figure 39.3 (a) Multiple myeloma affecting the left humerus with a pathological fracture. (b) Multiple myeloma with multiple deposits in the skull.

had previous radiotherapy. Chondrosarcoma (Figures 39.5, 39.6 and 39.7) and Ewing's sarcoma (Figure 39.8) make up most of the rest. Ewing's sarcoma occurs in adolescence, while the incidence of chondrosarcoma increases from middle age onwards.

Some conditions are associated with an increased likelihood of developing malignant disease in bone and/or cartilage (Table 39.1).

Soft tissue tumours are also quite rare and most are benign, with only one in a hundred being malignant (Figure 39.9).

Malignant tumours usually metastasise to bone by means of haematogenous spread. The spine is the third most common site for metastases, after the lung and liver. Although most patients with systemic cancer will have metastatic disease in the spine before they die, only 10 per cent are symptomatic.

Tumour cells metastasise to the spine via Batson's venous plexus. These retroperitoneal veins have no valves and allow retrograde embolisation to the spine and proximal long bones (Figure 39.10).

Figure 39.4 Sclerotic osteosarcoma of the distal femur in a child.

Metastases can be lytic, sclerotic or mixed. Lytic metastases usually arise from tumours that are vascular. However, they can also occur in very aggressive, destructive tumours with no healing response from the bone. Sclerotic lesions are commonly from the prostate.

BONE TUMOURS

Bone tumours are classified according to the tissue of origin. These include:

- metastases – may show histological features of their tissue of origin;
- haemopoietic tumours – e.g. myeloma;
- osteogenic tumours – e.g. osteosarcoma;
- chondrogenic tumours – e.g. chondrosarcoma;
- others – e.g. Ewing's sarcoma.

Sir James Paget, 1814–1899, surgeon, St Bartholomew's Hospital, London, UK, described osteitis deformans in 1877.

James Ewing, 1866–1943, Professor of Pathology, The Cornell University Medical College, New York, NY, USA, described this type of sarcoma in 1921.

Oscar V Batson, 1894–1979, an American otolaryngologist.

Figure 39.8 Ewing's sarcoma of the proximal fibula. The tumour is metadiaphyseal in location with a periosteal reaction and subtle onion-skinning.

Table 39.1 Conditions associated with an increased risk of malignant disease in bone and cartilage.

High risk	Moderate risk	Low risk
Maffucci syndrome (enchondromatosis and angiomas of soft tissue)	Diaphyseal aclasia (multiple osteochondromas)	Chronic osteomyelitis
Ollier's disease (enchondromatosis)	Polyostotic Paget's disease	Osteonecrosis
Familial retinoblastoma syndrome	Radiation osteitis	Fibrous dysplasia, osteogenesis imperfecta, osteoblastoma and chondroblastoma

METASTASES

The vast majority of tumours spreading to the skeleton are carcinomas; but not infrequently the primary tumour is never found.

Metastases are rare in children, but can occur from neuroblastoma, rhabdomyosarcoma and clear cell carcinoma of the kidney (Summary boxes 39.1 and 39.2).

Summary box 39.1

Most common bone metastases (93 per cent)

- Breast
- Prostate
- Lung
- Renal
- Thyroid

Figure 39.9 (a) Large, fungating soft-tissue sarcoma of the buttock. (b) Magnetic resonance imaging confirmed its extent.

Figure 39.10 Common sites of metastatic bone disease.

Summary box 39.2

Most common sites of bone metastases

- Spine
- Proximal femur
- Proximal humerus

HAEMOPOIETIC TUMOURS

There are no benign neoplasms of the haemopoietic system. Malignant tumours can be divided into two groups:

- 1 solitary plasmacytoma/multiple myeloma (Figure 39.2);
- 2 lymphomas; malignant neoplasm of the lymphoid cells (Summary box 39.3).

Summary box 39.3

Malignant bone tumours

- Plasmacytoma – solitary form of multiple myeloma
- Osteosarcoma – often secondary to Paget's disease and radiotherapy
- Chondrosarcoma
- Ewing's sarcoma

OSTEOGENIC TUMOURS

These tumours produce osteoid or bony matrix.

Osteoid osteoma (Figures 39.11 and 39.12) is a benign bone-forming lesion which is small but very painful. Usually, symptoms occur at night and are typically relieved by anti-inflammatories. Children and adolescents are frequently affected. They can occur in any bone but are common in the proximal femur.

Figure 39.11 X-ray showing an osteoid osteoma of the tibial diaphysis with reactive bone formation.

Figure 39.12 (a) Axial computed tomography (CT) scan showing an osteoid osteoma nidus in the distal tibia. (b) CT-guided radiofrequency thermocoagulation of an osteoid osteoma of the distal tibia. The scan shows the electrode *in situ*.

Osteoid osteomas are usually diaphyseal in location and give rise to a dense cortical reaction (Figure 39.11). Osteoblastoma is the larger more aggressive counterpart of osteoid osteoma that commonly occurs in the spine.

Osteosarcoma (Figures 39.3 and 39.4) is most common in the distal femur, followed by proximal tibia, proximal humerus and distal tibia.

Radiologically and histologically the tumour can be sclerotic (Figure 39.3), chondroblastic, teleangiectic and other more unusual histological forms. Usually, osteosarcomas are intraosseous, but they can also arise from the surface of the bone. Paraosteal osteosarcoma (Figure 39.13) is a low grade osteosarcoma that arises from the surface of the bone. It frequently affects the distal femur and proximal tibia. The clinical symptoms are often mild and long-standing (Summary box 39.4).

Summary box 39.4

Tumours producing bone

- Osteoid osteoma – small painful; produce dense cortical reaction
- Osteoblastoma – larger and more aggressive than osteoid osteoma
- Osteosarcoma – malignant; most commonest in lower femur and upper tibia

CHONDROGENIC TUMOURS

These tumours produce chondroid matrix. The biological spectrum of these tumours ranges from very benign to highly malignant.

Osteochondroma (Figures 39.14 and 39.15) is a benign cartilage capped bony projection. It is thought to originate from the physis. The bony projection is always growing away from the joint; towards the diaphyseal region of the bone. It has no structures attached to it. Osteochondromas can be pedunculated or sessile. The stalk or base is always continuous with the intramedullary cavity of the bone. They are usually solitary, but can be multiple (Figure 39.16) in diaphyseal aclasia (autosomal dominant inheritance). Complications include mechanical symptoms, nerve impingement, vascular pseudoaneurysm, fracture and infarction. Increasing size or pain, particularly after skeletal maturity, is concerning and may indicate malignant

Figure 39.13 Paraosteal osteosarcoma of the distal femur in an unusually young patient. There is no continuity between the tumour and the intramedullary cavity of the femur.

Figure 39.14 Pedunculated osteochondromas of the proximal fibula with pseudarthrosis. Osteochondromas always grow away from the physis and are in continuity with the intramedullary cavity of the bone it arises from.

Figure 39.15 Excised pedunculated osteochondroma showing cartilage cap.

Figure 39.16 Multiple osteochondromas in diaphyseal aclasia.

transformation. The incidence of malignant transformation is less than 1 per cent in solitary osteochondromas and 1–3 per cent in diaphyseal aclasia.

Enchondroma (Figure 39.17) is a benign cartilaginous neoplasm within the intramedullary cavity of bone. Approximately 50 per cent are in the hands and feet. Enchondroma is the most common bone tumour in the hand. A large proportion of these tumours are entirely asymptomatic, and diagnosis is often incidental. They can present with pain, swelling or pathological fracture.

Patchy calcification, expansion and scalloping can be visible on the x-rays, but some are only diagnosed on magnetic resonance (MR) scan.

Ollier's disease is a developmental condition characterised by multiple enchondromas. In Maffucci syndrome, the multiple enchondromas are associated with multiple angiomas. Malignant transformation to chondrosarcoma can occur in approximately 20 per cent of patients with Ollier's disease and is almost inevitable in patients with Maffucci syndrome.

Chondroblastoma (Figure 39.18) is a benign cartilage producing tumour that occurs in the epiphysis of children. It is most common around the knee. Pain is often severe with associated inflammation and possibly joint effusion. Radiologically, there is

Figure 39.17 Calcification and pathological fracture in a benign enchondroma of the proximal phalanx of the ring finger.

Figure 39.18 (a) Lateral x-ray with barely visible chondroblastoma in the epiphysis of the proximal tibia. (b) Coronal T2-weighted magnetic resonance imaging scan showing chondroblastoma in the epiphysis of the proximal tibia with surrounding oedema. (c) Sagittal computed tomography reconstruction showing calcification within a chondroblastoma of the proximal tibial epiphysis.

an often barely visible lytic lesion in the centre of the epiphysis. The diagnosis is often missed, and bone scan can aid in the localization of the lesion.

Chondrosarcoma (Figures 39.5, 39.6 and 39.7) is a malignant tumour with cartilage differentiation. The biological spectrum is very wide; it ranges from very low grade lesions to highly aggressive dedifferentiated tumours. Clinically, the presenting symptom is pain and/or swelling. Symptoms are often long-standing. Radiological and pathological correlation is particularly important in the evaluation of this condition. Clear cell chondrosarcoma is a rare form of chondrosarcoma that occurs in the epiphysis (Figure 39.19 and Summary box 39.5).

Summary box 39.5

Tumours producing cartilage

- Osteochondroma – cartilage capped; grows away from physis
- Enchondroma – inside bone; most common in hands and feet
- Chondroblastoma – in epiphyses of adolescents
- Chondrosarcoma – of varying malignancy

OTHERS

Simple bone cyst, or unicameral bone cyst (Figure 39.20), is a membrane-lined cavity filled with serous fluid. It usually occurs in proximal long bones of children.

Aneurysmal bone cyst (Figure 39.21) is a benign cystic lesion of bone consisting of blood-filled spaces separated by fibrous septa. The lesion is much more aggressive than a simple bone cyst and often presents with pain and swelling. Plain x-rays show commonly aggressive features with eccentric expansion of the cortex and an open physis. Scans often show multiple fluid levels (Figure 39.20).

Giant cell tumour of bone (Figure 39.22) is a benign aggressive tumour with large osteoclast-like giant cells. It usually occurs between the ages of 20 and 45, when the physes have closed. Giant cell tumour typically affects the epiphysis of long bones, especially around the knee, proximal humerus and distal radius.

Eosinophilic granuloma is a rare neoplasm of Langerhans cells (Figure 39.23). It can be unifocal (eosinophilic granuloma), multifocal (Hand–Schuller–Christian disease) or disseminated (Letterer–Siwe disease). There is a predilection for the skull and diaphyses of long bones. In the spine it can present with collapse, known as vertebra plana. X-rays can appear aggressive and similar to Ewing's sarcoma.

Fibrous dysplasia (Figure 39.24) is a benign fibro-osseous lesion that can be monostotic or polyostotic. It usually affects the long bones, ribs and skull. Patients can present with pain, swelling and or fracture. Hip fractures can produce a shepherd's crook deformity. Radiologically, there is often expansion and a ground glass appearance. Cysts may well be present.

Ewing's sarcoma (Figure 39.8) is a round cell sarcoma of bone. It tends to arise in the diaphyses of long bones or the pelvis. Patients usually present with a painful mass and may have general symptoms with fever, anaemia and increased erythrocyte sedimentation rate (ESR). Radiologically, the bone appears moth-eaten and may show an 'onion-skin' periosteal reaction. There is often significant inflammation with oedema on the MR scan.

Figure 39.19 (a) Clear cell chondrosarcoma of the medial femoral condyle. (b) Sagittal T1-weighted magnetic resonance imaging scan showing clear cell chondrosarcoma in the medial femoral condyle. (c) Computed tomography scan reconstruction shows calcification within the lesion.

Figure 39.20 Pathological fracture through a simple bone cyst with the pathognomic fallen leaf sign. The fracture healed and the cyst consolidated without operative intervention.

Bone tumours can also be classified according to their site (Table 39.2). Epiphyseal tumours are likely to be benign (Table 39.3).

Bone tumours are usually staged using the Enneking staging system. Benign tumours are staged as:

- latent (i.e. osteochondroma);
- active (i.e. osteoid osteoma);
- aggressive (i.e. giant cell tumour).

Latent lesions are usually asymptomatic and often discovered incidentally. Active lesions, such as osteoid osteoma, do present with mild symptoms and continue to grow. A giant cell tumour

Table 39.2 Classification of bone tumours by site.

Tumour and site		
Diaphyseal	Metaphyseal	Epiphyseal
Eosinophil granuloma	Most	Chondroblastoma
Osteoid osteoma		Intra-articular osteoid osteoma
Fibrous dysplasia		Giant cell tumour (physis closed)
Adamantinoma		Clear cell chondrosarcoma
Ewing's sarcoma		

Table 39.3 Common diaphyseal bone tumours according to age.

Age	Most common diaphyseal tumour
<10	Eosinophil granuloma
Teenage	Ewing's sarcoma
Adult	Lymphoma
>60	Metastasis/myeloma

is an example of an aggressive lesion. Aggressive lesions tend to grow rapidly.

For malignant tumours, the Enneking system combines stage and grade of a tumour (Table 39.4).

The compartment is the bone that is involved with the tumour. A tumour is extracompartmental when the tumour has breached the cortex of the bone as visible on plain x-rays. Most bone tumours are Enneking stage 2B at diagnosis (Summary boxes 39.6 and 39.7).

Figure 39.21 (a) Aneurysmal bone cyst with pathological fracture of the proximal tibia. (b) Magnetic resonance imaging scan shows multiple fluid levels.

Figure 39.22 Giant cell tumour of the distal radius.

Figure 39.23 (a) Eosinophilic granuloma of the scapula. (b) Computed tomography scan shows a 'punched-out' lesion. (c) Spontaneous resolution.

Table 39.4 The Enneking staging system for bone tumours.

Enneking staging of bone tumours		
Low grade	Intra compartmental	1A
	Extra compartmental	1B
High grade	Intra compartmental	2A
	Extra compartmental	2B
Any grade	Metastases	3

Summary box 39.6

Other bone tumours

- Simple bone cyst – proximal long bones of children
- Aneurysmal bone cyst – more aggressive, expanding
- Giant cell tumour – found in epiphyses around the knee
- Fibrous dysplasia – may be multiple; found in long bones, ribs and skull
- Ewing's – round cell sarcoma; patients may have fever and anaemia

Summary box 39.7

Warning signs – bone tumour

- Non-mechanical bone pain
- Especially around the knee in young adolescents
- Concerning x-rays

Figure 39.24 Fibrous dysplasia affecting the left proximal femur. There is expansion of the bone with a ground glass appearance.

SOFT TISSUE TUMOURS

These tumours are also classified according to the cell of origin. Most types have a benign and malignant counterpart (i.e. lipoma (Figure 39.25) and liposarcoma). The biological spectrum of these tumours is wide and full multidisciplinary assessment essential to make a correct diagnosis.

Figure 39.25 (a) Coronal T1-weighted magnetic resonance imaging scan showing a benign lipoma deep to the quadriceps muscle. (b) Excised benign lipoma.

The Trojani system, based on tumour differentiation, mitotic count and tumour necrosis, is often used to grade soft tissue tumours. The TNM system is used for staging (Summary box 39.8).

Summary box 39.8

Warning signs – soft tissue tumour

- Larger than 5 cm
- Increasing in size
- Painful
- Deep to the fascia
- Recurrence after previous excision

HISTORY AND EXAMINATION/ INVESTIGATIONS/DIAGNOSIS INCLUDING DIFFERENTIAL

In the assessment of musculoskeletal tumours, a multidisciplinary approach that allows clinical, radiological and pathological correlation is essential to establish a correct diagnosis.

Treatment of primary bone and soft tissue tumours should only take place in an institution that has a full multidisciplinary team (centre of excellence).

When a musculoskeletal tumour is suspected:

- Stop
- Think
- Stage.

History and examination

Bone tumours

Non-mechanical and/or night pain, particularly in the young adolescent, are concerning symptoms and a primary bone tumour should be suspected. Symptoms that resolve with aspirin are suggestive of an osteoid osteoma.

Principles of management of primary bone tumours:

- high index of suspicion;
- early referral to a tumour centre;
- careful imaging studies;
- biopsy after completion of imaging investigations;
- minimally invasive technique for biopsy;
- multidisciplinary approach to management.

Patients with a past medical history of malignancy who present with back pain should be considered to have metastatic disease until proven otherwise. Plain x-rays of the spine and routine blood tests are the minimum that is required.

For metastatic disease of bone:

- the extent of metastases is best demonstrated on bone scan;
- prophylactic treatment of any impending fracture should be considered;
- radiotherapy and internal fixation improves pain and quality of life;
- beware the 'solitary' metastasis. This could be a primary bone tumour and full staging, including biopsy, is required.

Multiple myeloma (Figure 39.2) is the most common primary malignancy of bone in adults:

- It should be considered in all patients with back pain over 65 years of age
- Back pain with an ESR >100 mm/hour is multiple myeloma until proven otherwise
- Monoclonal gammopathy is diagnostic
- Elevated urinary and serum Bence Jones proteins are diagnostic.

Soft tissue tumours

Soft tissue swellings are common and the vast majority are benign. Symptoms and signs that suggest malignant disease are:

- pain;
- size: larger than 5 cm and/or increasing;
- position: deep to fascia;
- behaviour: recurrence after previous excision (whatever the pathology).

Each of these factors has a 25 per cent risk of malignancy.

Staging

Primary musculoskeletal tumours should be staged according to local and distant features:

- Local
 - Plain x-rays of the whole affected bone or soft tissue lesion (Figure 39.1);
 - MRI whole affected bone or soft tissue lesion
 - computed tomography (CT) scan;
 - ultrasound scan (for soft tissue tumours only).
- Distant
 - blood tests: including blood count, ESR, profile, calcium and myeloma screen;
 - plain x-rays of the chest;
 - CT scan of the lungs;
 - bone scan (for bone tumours only);
 - ultrasound scan abdomen (if renal metastasis is a possibility).
